INDEX TO VOLUME I., 1929.

REFERENCES AND ABBREVIATIONS

Readers in search of a given subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral, Heart and Cardiac, Liver and Hepatic, Child and Infant, Goitre and Thyroid, Diabetes, Glycosuria and Sugar, Eye, Ophthalmic, and Vision, Lunacy and Mental Disease, Arsenobenzol and Salvarsan, &c., &c., and that regional headings are more frequently used than pathological. Institutions and Corporations with the right to the prefix Royal will be found under that prefix, with the exception of Hospitals, which will be found under that heading; and Medical Societies, which are separately indexed under Societies. All Universities are indexed under the word University. (A.) = Annotation, (C.) = Correspondence, (N.I.) = New Inventions, (L.A.) = Leading Article, (M.L.) = Medico-legal, (M.T.T.) = Modern Technique in Treatment, (O.) = Obituary, (P.I.) = Parliamentary Intelligence, (R.) = Review, (R. and A.R.) = Reports and Analytical Records, (A.D.) = Clinical Interpretation of Aids to Diagnosis, and (N.P.) = New Preparations.

A Concordance of page numbers and dates of Issue will be found at the end of the Index.

A

Abdomen, pitfalls in the right side of the (H. W. Carson), 802
Abdominal disorders, Hunterian lecture on treatment of some acute (R. J. McNeill Love), 375; surgery, upper, local anæsthesia in (Charles A. Pannett) (Hunterian lecture), 271; (C.), 362, 416, 468, 579, 580; wall, post-operative rupture of (A.), 1260
Abel, A. Lawrence, Œsophageal Obstruction (R.), 669
Aberdeen City, M.O.H.'s report, 1327; County, M.O.H.'s report, 1328; hospital scheme, 303; Joint Hospital Fund, success of, 792
Abergele Sanatorium, 308
Abortifacients, advertisements of (M.L.), 464
Abortion, artificial, indications for, 154; criminal, and measures necessary to reduce the sale of abortifacients, discussion on, 233; (L.A.), 242; acquittal on charge of (M.L.), 736; induction of, from the psychiatric standpoint (Bernard Hart), 658; and premature labour, medical indications for induction of, discussion on, 666
Accessory food factors, alleged toxic action of (J. Clifford Hoyle), 734; (C.), 1223
Accident treatment, hospital claims for, 519
Accidental hæmorrhage, ætiology of (A.), 512
Accidents: anti-accident work in Berlin, 626; fatal, in streets of Paris, 576; in the coal industry (P.I.), 1068; in factories and workshops (P.I.), 691; motor, hospitals and, 745; ski-ing, note on frequency of (W. Knoll), 332, 426; street, deaths in London, 632; hospitals and, 250, 971; traffic, in Denmark, 1178
Acécoline (N.P.), 1178
Acetyl-choline, 1287; therapeutic application of (Maurice Villaret and L. Justin-Besançon), 493
Achlorhydria in infancy and childhood, significance of, 718
Acidophilus bacillus blocks, M-A-B (N.P.), 1126
Acidosis, post-operative (R. D. Lawrence), 286
Acoustic apparatus, 411
Acromegaly, case of, 554
Actinomycosis of appendix, case of (Frances M. G. Sinclair and S. C. Dyke), 73
Adenoids and enlarged tonsils (Board of Education's Medical Committee Interim Report), 355
Adrenaline and vasopressin, 1180
Africa, South, medicinal waters of, 270; plague menace in (A.), 457
Age, Life, and Death, Aspects of (Sir Humphry Rolleston, Bart.) (R.), 26
Age of Marriage Bill (P.I.), 420
Aircraft in the service of health, 538
Air transport of invalids (C.), 105
Albichthon ointment (N.P.), 856
Albuminuria (J. C. Spence) (A.D.), 623
Alcohol and Human Life (Courtenay C. Weeks) (R.), 1307; in therapeutics, 799; intravenous injection of (A.), 1263; medicinal use of, in the United States, 943
Alcoholism as an international problem, 1149
Alexander Memorial Prize, award of, 904
Alexander, Sidney, Injection treatment of varicose veins (C.), 521
Alexandra Day, 1105
Algiers and Algeria: From Cloud to Sunshine (Alfred S. Gubb) (R.), 450
Aliens, medical examination of female (P.I.), 586
Allbutt, Sir Clifford, memorial bronze portrait of (A.), 1043
Allergic phenomena in rheumatism, 644
Allison, S. F., and Peters, B. A., Intranasal immunisation against scarlet fever, 1035
Allsoy biscuits, Johnson's (N.P.), 1178
Alport, A. Cecil, Splenic anæmia: the necessity for early operation, 864
Ambulance aeroplanes, 1001, 1002, 1389; service, the home (A.), 1155
America, public health reports in, 155
American Medical Association of Vienna: 25th Anniversary Number: Ars Medici (R.), 82; Surgeon-General, annual report of, 737
Anæmia of pregnancy and the puerperium, severe (William Evans), 14; pernicious, liver treatment of, 925, red cells in (A.), 1261, treatment of, 628; secondary, liver therapy in (S. C. Dyke), 1192; (A.), 1206
Anæmias, occupational (A.), 786
Anæsthesia, avertin for (Joseph Blomfield and F. E. Shipway), 546, 635
Anæsthesia, deaths under, two (M.L.), 99; general, by intravenous injection of ethyl alcohol (Julien D. Constantin), 1247; local (C. Abbott-Brown) (C.), 1278, in upper abdominal surgery (Charles A. Pannett) (Hunterian lecture), 271; (C.), 362, 416, 468, 579, 580; Regional (Gaston Labat), 2nd ed. (R.), 880, 928; research on: the Hickman memorial (A.), 787; Spinal (C. H. Evans) (R.), 1256, (L.A.), 291, 380, in abdominal surgery (C.), 468, 579, 580, note on (Charles A. Pannett), 1194
Anæsthetic fatalities, pathology of (A.), 514; masks, retention apparatus for (R. J. Clausen) (N.I.), 1035
Anæsthetics, intubation inhalation of, methods of (W. Howard Jones), 330
Anal and vulvar eczema, treatment of (Agnes Savill) (M.T.T.), 679, 731
Anaphylactic and allergic reactions, 1285
Anatomy, Lane's school of, 166
Anderson, Isaac Henry, Deputy Inspector-General R.N. (O.), 358
Anderson, John H., Medical management of a case of gastric or duodenal ulceration, 1347
Anderson, W., McCallum, J., and Magee, H. E., Diet and peptic ulcers in cavies, 12
Aneurysm of internal iliac artery, traumatic (W. H. C. Romanis), 500
Angina, agranulocytic, case of (Lindsey W. Batten), 440; (C.), 523; pectoris, ray treatment of (A.), 885
Animals, Protection of (Amendment Bill (P.I.), 259, 368
Anoxæmia, the effects of, 642
Anthrax from goat's hair, 1221; protection against (P.I.), 639
Antibodies in relation to immunity (L.A.), 1361
Antilles, parasitic problems in the Lesser (A.), 564
"Antiseptic, The": silver jubilee of the, 367
Antitoxin, concentrated (L.A.), 292
Antivirus, Besredka's, 1092; (A.), 1157
Anuria, calculous (H. P. Winsbury White), 918
Anxiety, psychopathology of, discussion on, 774
Aorta, dissecting aneurysm of the, case of (C. Vincent Patrick and John F. Taylor), 181
Appeal for Royal Surgical Aid Society letters (C.), 1072
Appendicitis, acute, 375; chronic (A.), 32, and some conditions which simulate it (H. N. Fletcher), 78; menace of (H. H. Greenwood), 973; operating for (C.), 465, 522, 580, 633; prevalence of (A.), 618; simulating other diseases, four cases of (Charles Flandin and J. Campbell Gilroy), 17; and intestinal obstruction, serotherapy in (A.), 934
Appendix, actinomycosis of (F. M. G. Sinclair and S. C. Dyke), 73; (C.), 159; shot in the vermiform (C.), 157
Appointments, weekly lists of, 55, 163, 213, 269, 318, 370, 425, 482, 533, 641, 694, 745, 801, 855, 906, 959, 1015, 1071, 1125, 1176, 1228, 1281, 1335, 1384
Armour, Donald J., on head injuries, 1212; and Souttar, H. S., Radium treatment of cancer in France and Belgium, 299
Armstrong-Jones, Sir Robert, appointed Sheriff for Carnarvonshire, 694

683550

Army, health of the, 458; in India, prevention of disease in the (A.), 294; medical men and the (P.I.), 526; medical records in the (P.I.), 530
Army Medical Services, the (A.), 198
Aron, Max, Vie et reproduction (R.), 1307
Arrhythmias, Cardiac (Irving R. Roth) (R.), 133
Arris and Gale lecture on lysozyme (A. Fleming), 217
Ars Medici (American Medical Association of Vienna) (R.), 82
Arsenical poisoning, acute, discussion on, 1146
Arteriography: is it permissible in practice? 1060
Arthrites Gonococciques, Les (Henri Mondor) (R.), 132
Arthritic muscular atrophy, investigation into cause of (A. E. Beryl Harding), 433, 804; (A.), 454; (C.), 520
Arthritis, Chronic (Non-tuberculous) (A. G. Timbrell Fisher) (R.), 132, rheumatic (L.A.), 403, tonsillectomy in (A. B. Pavey-Smith), 170; (C.), 363, 468, 580; deformans and accidents (A.), 676, experimental (A.), 295; multiple, infection in (A.), 513; rheumatoid, research on, 531
Artificial silk industry (P.I.), 316
Asbestosis (P.I.), 315
Asthma, allergic and psychical factors in (Karl Hansen), 443; inquiry into: observations at Edinburgh, 517; research (A.), 36; (C.), 158, 209, 264, 306, 360, 415, 416
Asthma Research Council (C.), 106, appeal (C.), 50
Astley-Ainslie Institution, Lt.-Col. J. Cunningham appointed medical superintendent, 107
Asymmetry in the animal body, 961
Atkinson, Edward Leicester (O.), 479
Atophan in a case of gouty chemosis (V. St. L. Pinnock), 921
Auden, Arnold William Montfort (O.), 637
Auden, G. A., Congenital dislocation of the hip (C.), 687
Auricle, rupture of left (Frederic W. Longhurst), 873
Auricular fibrillation, cause of (A.), 405
Auricular flutter after diphtheria in a child (Patrick O'Donovan), 607; (C.), 687

AUSTRALASIA, CORRESPONDENCE FROM.—Bush nursing centres, 45—Canberra, new Institute of Anatomy at, 1378—Cancer campaign in Queensland, 464, treatment of, in New Zealand, 945—Hospital maintenance in Australia, 44—Mental deficiency in New Zealand, 945—National Insurance Bill, 44—New Zealand, health of, 945—Noise Abatement League in Melbourne, 45—Noise and health, 945—Pacific Science Congress, 1378—Sydney University, new chairs in, 1377—Venereal disease, 945

Australian surgeons in congress (A.), 1046
Autopsies in hospitals, 943
Avertin anæsthesia, non-recovery after (A.), 1365; rectal narcosis with, 448; use of, for anæsthesia (J. Blomfield and F. E. Shipway), 546, 635
Aviation in the service of medicine, 1113
Aviators, night vision of, 319
Azuero treatment, the (C.), 1284

B

Babies' Club, first annual meeting, 484
Bacillus abortus infection in Scotland, case of (A. T. Todd), 388; *and see Brucella abortus*
Bacillus aerogenes capsulatus, case of puerperal infection due to (Frances Ivens), 606
Bacillus funduliformis, septicæmia due to (A.), 991
Bacillus morbificans bovis (Basenau), case of infection with (S. H. Warren), 660
Bacillus welchii, case of puerperal infection with, 1305
Back, manipulation of the (James Mennell), 746
Back pain, low (M. Smith-Petersen), 501; surgery of (L.A.), 1153
Bacon, Gorham, and Saunders, Truman Laurence, Manual of Otology, 8th ed. (R.), 1040
Bacteria, employment of, in modern warfare (C.), 741, 793, 845, 846; Morphologic Variation and Rate of Growth of (A. T. Henrici) (R.), 779
Bacteriology (Fred Wilbur Tanner) (R.), 879; and the Study of the Infections, Recent Advances in (J. Henry Dible) (R.), 289; for Nurses, Applied (Jean Martin White) (R.), 1040; of a series of uteri removed at operation (Elizabeth H. Lepper and Marjorie Martland), 492; Practical (Fred W. Tanner) (R.), 722

ON

RADIOLOGY FROM A SURGEON'S STANDPOINT.

Delivered before the Institute of Radiology

BY W. SAMPSON HANDLEY, M.S. LOND., F.R.C.S. ENG.,

SENIOR SURGEON TO THE MIDDLESEX HOSPITAL.

FOR the privileged position I occupy on this occasion I can at least claim one qualification—namely, that the span of my professional life coincides almost to a year with the history of radiology so far as it has yet been written. In 1896 the present Sir Frederick Hopkins, then on the teaching staff of Guy's Hospital, as an enthusiastic amateur of the new science, had acquired a primitive X ray set. At his request and in my capacity of house surgeon I collected a group of five cases supposed with varying degrees of probability to have needles embedded in their hands. As the screen had no dark camera attached it was necessary to turn the gas very low, ignoring the offensive fumes which the Argand burner under such conditions produces. Moreover, the insulation of high tension wires was at that date absent or imperfect. The demonstration was successful; an embedded needle was clearly seen in every case, and was marked upon the skin. In other words, five cases, previously undiagnosable, were diagnosed by the new method. The patients were told to come up for operation next day, but not a single one returned to the scene of the diabolical séance at which he had assisted, where in a dark and evil-smelling chamber there had appeared before him a mysterious green globe of light, the operation of which was attended by painful electric shocks and by the awful vision of his own skeleton.

It seems difficult to believe that the distance separating this primitive phase from the radiography of the present day with its instantaneous deep pictures, and its powers of recording the phases of moving viscera such as the stomach and the heart, can have been traversed in the short space of 35 years. I note in passing that the first motion pictures of the heart and limbs were produced in this country by Dr. Russell Reynolds.

The progress made would have been impossible without the coöperation of the physicists, among whom the first President of the Rontgen Society, after whom the present lecture is named, must ever hold an honoured place. To-day the physicist is more-eminent as the authentic medicine-man of the tribe. His achievements paralyse our powers of wonder, otherwise they would become intolerable. Moving confidently about in a universe totally unappreciable to any of his senses, at one moment burrowing in the interior of an atom, at another creating vast, and some think unnecessary, disturbances in the all-pervading ether, he has asserted his mastery and proved his incredible statements by making the electron the humble servant, messenger, musician, artist, and plaything of man. It is becoming clear that in some respects the imaginative faculties of a poet compared to the disciplined imagination of a great scientist are as a child's first lispings compared to the rational utterance of a grown man.

A special word of recognition is due to that very small band of physicists who have forsaken the cold joys of pure intellection to serve sick humanity. I may be allowed to recall with satisfaction that the Middlesex Hospital, which I have the honour to serve, was the first hospital to appoint a physicist upon its staff in the person of Prof. Sidney Russ, and St. Bartholomew's Hospital in the appointment of Prof. F. L. Hopwood has followed this sound example. To the pioneers of medical radiology who plunged into the unknown territory determined to fathom its secrets at any cost, sufficient honour can never be paid. Many of them continued their work long after they knew the inevitable penalty of doing so. And on this occasion, with a sense of loss which the lapse of time fails to dull, I recall the memory of my friend Cecil Lyster. During the past year radiology has suffered a heavy loss in the death of Dr. Robert Knox. He was wise in council with that mixture of enterprise and caution which is the mark of his countrymen, skilful with his pen, cautious in his judgments, systematic and original in his method of work. In the judgment of the world outside, as well as in that of Britain, he was at the time of his death one of the foremost radiologists.

THERAPEUTIC RADIOLOGY.

Time will not allow me to recount the advances of diagnostic radiology which in recent years have made the thorax and the skull as transparent as the limbs. It may still be doubted whether some medical practitioners make use of diagnostic radiology to the full extent demanded by the interests of their patients. But the advance made can be measured by one simple fact. The doctor nowadays who treats a fracture or a severe sprain without insisting upon a radiograph places himself out of court.

Recent years have seen a striking enlargement of the field of therapeutic radiology, and I cannot attempt a systematic survey of the progress made. Confining myself to diseases which come under the surgeon's eye I have first to consider certain non-malignant but precancerous conditions.

Chronic Mastitis.

Chronic mastitis is of special interest to me because I believe I was the first to advocate its treatment by X rays in a paper on the prophylaxis of breast cancer contributed to the *Practitioner* in April, 1910. It may be said to-day that X rays have fully established their position as the most effective therapeutic agent for chronic mastitis. In support of this opinion I could call in the authority of a number of well-known radiologists, with whom I have been associated in the treatment of cases, and especially of Dr. G. B. Batten, Dr. Russell Reynolds, Dr. Douglas Webster, and Dr. Stanley Melville. A long course of treatment is not as a rule required. Not only do X rays relieve pain, but the mastitic swellings frequently disappear entirely and the breast returns to the normal. Radiation is, however, comparatively ineffective in the cystic form of the disease, and for this when it occurs in middle age operation is still often necessary. X rays may aggravate subacute mastitis and must be used with great caution in this condition. In acute mastitis they are contra-indicated. Among the large number of cases of chronic mastitis which I have sent for X ray treatment there are three who developed cancer in the breast during or after the treatment. But for some years past no such case has occurred, a token, I think, of the increased efficiency of X ray treatment.

Chronic mastitis, or duct catarrh of the larger ducts which is closely allied to it, is a frequent precursor of cancer of the breast, and significantly affects by choice the same quadrant of the breast, the upper and outer one. In duct catarrh of the breast certain of the main ducts are choked by masses of shed epithelium, the product of the undue activity of their lining membrane. The ducts near the nipple are palpable as tortuous cords. Around the affected ducts there is newly formed fibrous tissue associated with areas of round-celled infiltration. The contraction of this fibrous tissue produces four clinical danger signals—namely, (1) axial deviation of the nipple; (2) retraction of the orifices upon the nipple of one or more of the affected ducts; (3) slight elevation of the nipple; (4) perhaps slight flattening of the nipple. When these signs appear, even though there may be no lump in the breast, the imminent onset of a cancer

should be feared. The appearance of white dots upon the nipple is significant. These dots are the ends of the cylinders of epithelial debris which fill the affected ducts, and may sometimes be squeezed out of them by digital pressure.

I am very hopeful that in cases where the danger signals I have mentioned are present the timely administration of a course of X rays of some penetrative power will avert the development of cancer. I saw recently a case in which three years previously I removed the right breast for a precancerous mastitis. The remaining breast now shows danger signals, though no tumour is present. I am sending her for X ray treatment and hope thus to avert the threatened onset of a carcinoma. I believe there is a large and hopeful field for the employment of X rays as a preventive of breast cancer in women with a family history of the disease, and in those presenting signs of chronic mastitis or duct catarrh.

Papillomata.

In duct papilloma of the breast I am unable to record success from X ray treatment. If, however, the papilloma can be localised removal of the breast can often be averted by the use of buried radium tubes. Multiple papilloma of the colon usually ends in carcinoma and no effective treatment is known. Is it not possible that it might be successfully attacked by X rays or by the swallowing of radon capsules?

THREE PERIODS OF X RAY THERAPY.

Looking back over the history of therapeutic X rays during the past 30 years three periods can be traced.

The *first period* of inadequate and tentative dosage, sometimes successful in destroying a primary growth, but rarely averting dissemination. X ray treatment of this first period in my opinion established its value as a prophylactic of recurrence, but to a limited extent only. In alliance with improved methods of operation it almost abolished local recurrence after breast operations, but it showed itself powerless to prevent the deeper parasternal deposits arising from the glands of the internal mammary chain. I have lately shown that in a large percentage of cases of breast cancer these glands are infected prior to operation.

The *second period* of X ray therapy was ushered in by the discovery of the Coolidge tube and the exploitation at Erlangen of the utmost power the tube could supply or the patient withstand. The high hopes which the method inspired have been shattered, and the words of caution uttered by leading British radiologists, and especially by Knox, have been fully justified. On at least three occasions I have seen fresh secondary nodules appear on an area which had been subjected within the previous three months to intensive X ray treatment. In the following case intensive X ray treatment seemed clearly to have stimulated a growth and perhaps to have aroused into activity a second primary growth.

Miss H. noticed a lump in the left breast in 1924. The breast was removed by her doctor. In January, 1928, an enlarged right axillary gland was felt. Intensive X ray therapy was begun and was continued for six months. The patient then ceased to attend, finding that her condition was getting worse. While she was under treatment the right breast became hard, and a rash appeared extensively over the chest. When I first saw her on July 31st, 1928, she had an ulcerated right nipple with a subjacent growth having the characters of a second primary growth. A recurrent lump was present just below the left axilla in the operation scar. An extensive nodular erythematous rash covered the front of the chest and extended into the left axilla. It had a definitely raised edge, and in the axilla its lower margin formed a right angle which appeared without any doubt to mark out the lower limit of an area of X ray exposure.

It is agreed by dermatologists that a right angle seen in a skin lesion marks it as "factitious" and this case comes under that rule.

The *third period* of X ray therapy dates from the recognition of the failure of Erlangen methods. The great power of the modern tube is now used in divided doses which do not produce vomiting or other undesirable constitutional symptoms. These methods are justifying themselves by a progressive increase in the power of X ray treatment to control and prevent recurrence. I note particularly that I have recently seen several cases where the advance of nodular deposits of breast cancer, widely spread over the chest and abdomen, has been arrested. Successes have also been recorded in the treatment of primary breast cancers by X rays alone, and I have myself seen such cases. But even after the disappearance of the primary growth the appearance of secondary foci may falsify the hopes first raised.

RADIUM.

The discovery of radium by the Curies, a characteristic triumph of French logic and perseverance, opened out new vistas in radiology. Radium rays proved themselves to be much more effective in quality than the X rays available at that time, and to a certain extent I believe this is still true. But the principal advance was this, that it became possible for the first time to introduce the focus of radiation within the body and thus to maximise the dose of radiation received by the diseased area and to minimise the dose received by the rest of the body. To secure this characteristic advantage of radium to the full a new branch of surgery has arisen which has received the name of radio-surgery, and except in growths on the surface the use of buried radium tubes, first introduced by Dominici, seems likely to supersede surface radium treatment.

Radio-Surgery.

In regard to radio-surgery the most interesting question of the moment is the proper therapeutic adjustment of two variables, the amount of radium buried, and the time it is left in. Shall a high intensity of radium radiation be used for a short time, say 24 hours, or a low intensity for a long time, say a week? At the Middlesex Hospital, partly because of the operation of a rota for the use of radium by different members of the staff, the large quantity short time method has been in use. In some forms of growth—for instance, in bone sarcomas and in the sternal deposits of breast cancer—it has given excellent results. In growths of the tongue Prof. C. Regaud's observations in Paris show that the prolonged low-intensity method is much the more effective.

The results obtained in cancer of the tongue at Westminster Hospital by Mr. Arthur Evans and others with even smaller amounts of radium are, I understand, very good. At St. Bartholomew's Hospital Mr. Geoffrey Keynes has used a prolonged low-intensity method as a substitute for operation in breast cancer, and with promising results. He has shown that it is possible, using only a moderate amount of radium, to deal effectively with a large area of tissue. Thus the prolonged low-intensity method, as compared with the short high-intensity method, would seem to have definitely proved its superiority in squamous carcinoma and in some glandular cancers. Sir C. Gordon Watson has made a systematic attempt to apply the prolonged low-intensity method to rectal cancer.

And here I must confess that at the Middlesex Hospital we have been in this respect slow to draw practical conclusions from the results of our own research laboratories. The time-quantity ratio for any given number of milligramme-hours was first shown to be of importance in treatment by Prof. Lazarus Barlow, and I believe that his results inspired to some extent the methods which Regaud has successfully adopted for cancer of the tongue at the Radium Institute in Paris. It was shown by Lazarus Barlow that cells in a state of active division are about seven times more sensitive to radiation than resting cells. The necessity of prolonging the radiation period so as to cover, if possible, the division of every cell of a malignant mass is thus indicated, and is insisted upon by Regaud. Lazarus, Barlow also compared the effects of quantitatively identical gamma-ray

610.5
LA
1929

bombardment upon squamous and upon columnar epithelium, according as the quantity of radium was large and the time of exposure small, or the quantity of radium was small and the time of exposure large. For squamous epithelium the prolonged low-intensity treatment was the more effective. Clinical observations have confirmed these results for squamous carcinoma beyond the possibility of doubt.

Prophylactic Use of Radium.

It is now about seven years since I realised that the internal mammary glands which lie along the internal mammary artery just outside the edge of the sternum are infected by breast cancer at about the same time as the axillary glands. About seven cases out of ten have enlarged axillary glands when they first come for advice. Thus in 70 per cent. of cases, when it first comes into the surgeon's hands, breast cancer is an intrathoracic disease. Since I recognised this fact and met it by burying a line of radium tubes at the time of operation along the line of the internal mammary glands, the percentage of my cases free from recurrence at the end of three years has gone up from 47 to 56.

The Stimulating Effect of Small Doses.

I now approach a subject of great difficulty, and one which appears to require increased attention from radiologists. I refer to the possibility, which from my clinical experience appears almost a certainty, that very small doses of radiation may exert a stimulating effect upon the cells of a malignant growth, and may thus do harm instead of good. The suggestion is that if a radium tube is placed for a certain time in a field of tissue already impregnated with isolated and latent carcinoma cells, the field will differentiate itself into three zones: (1) a central circle or zone where carcinoma cells are destroyed; (2) an inner zone where the carcinoma cells, though not killed, are inhibited; (3) an outer zone where the carcinoma cells are stimulated to more rapid growth. Abbé, experimenting with bean embryos, found that a minimal dose of radium stimulated growth, while increasing doses progressively retarded and finally arrested the growth of the embryo. Lazarus Barlow, working with ascaris ova, obtained similar results. These observations establish a primâ facie case for small dose stimulation of malignant cells by radiation, a phrase for which in the rest of this lecture I shall use for short the word "stimulation."

In my earlier work with buried radium tubes, now dating back nearly 15 years, it was my custom to implant the tubes in the centre of or beneath the palpable or visible nodule of malignant tissue. The usual result was the shrinkage or disappearance of the malignant focus. But within a few months the hopes thus raised were shattered by the appearance of fresh malignant nodules in the region immediately around. It seemed likely that this unsatisfactory result was due to the stimulation, by an inadequate dose of radiation, of an inappreciable and apparently healthy zone of microscopic invasion around the visible focus of disease. To meet this danger I adopted, and have since used, the plan of encircling the palpable focus of disease by a ring of radium tubes in order to sterilise the zone of microscopic infection.

In connexion with this question I now wish to draw attention to a case of recurrent breast cancer which presented two nodules close to each other, one above and one below the outer part of the scar (Fig. 1). On March 31st, 1928, a 25 mg. tube of radium bromide was buried just above the upper nodule and a similar tube just below the lower nodule for 24 hours. At this time these nodules were the only recurrent manifestations anywhere near the scar, but on April 8th a suspicion of nodular thickening was felt at a point four inches internal to the original nodules, and the same distance from the radium tubes. By May 2nd a line of definite nodules was present along the scar, the nearest nodule 2 in. from the focus of radiation, the furthest 4½ in. from it. The smallest nodules were the nearest one and the most remote one, the largest, was 4 in. from the focus. The nodules originally treated were reduced to fibrotic relics. A second tracing was made on May 18th. A new tiny nodule had now appeared 1 in. only from the focus. The other nodules had continued to grow, the original one being still the largest. By May 25th three new nodules had appeared, one of them 1¾ in. away from the focus, the other two 2½ in. away from it. Of the two remotest nodules, 4½ in. away, one had disappeared and the other was smaller.

If we assume that numerous quiescent depôts of cancer cells were present all along the scar at the

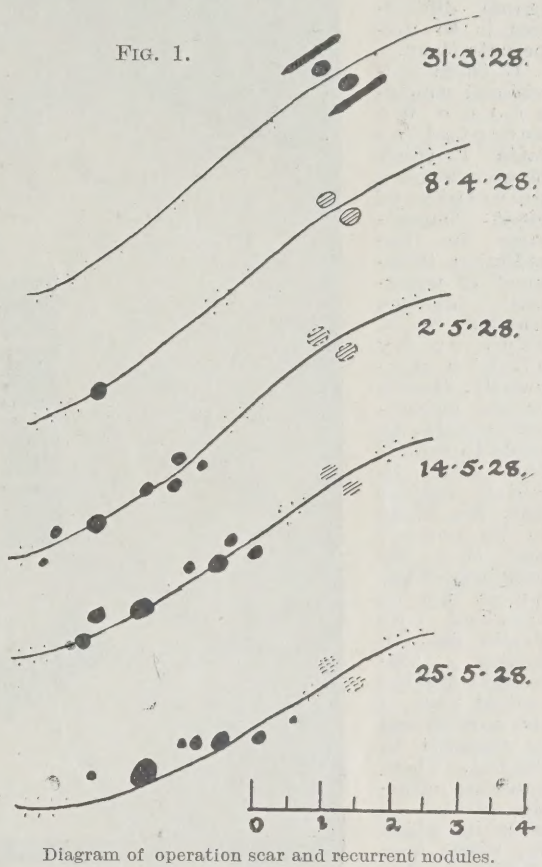

Diagram of operation scar and recurrent nodules.

time the radiation was given—a very reasonable hypothesis—and further assume that the subsequent developments were due to the action of the radium, we arrive at the following data. Two radium tubes each of 12·5 mg. shielded by 1 mm. of platinum and acting for 24 hours, give destruction or prolonged inhibition of cancer cells within a radius of about an inch. At a distance of 4 in. from the focus there is a maximal active stimulation of cancer cells, manifesting itself within eight days. After 32 days stimulation effects had shown themselves over a zone covering points situated between 2 in. and 4½ in. from the focus, but with a focus of maximum stimulation 4 in. from the focus. After 48 days stimulation, or mere failure of inhibition, was manifested at points as near as within one inch of the focus, while at the periphery of the field 4½ in. from the focus there was a suggestion that the stimulated nodules were again receding—i.e., that very weak doses of radiation have only a temporary stimulating effect.

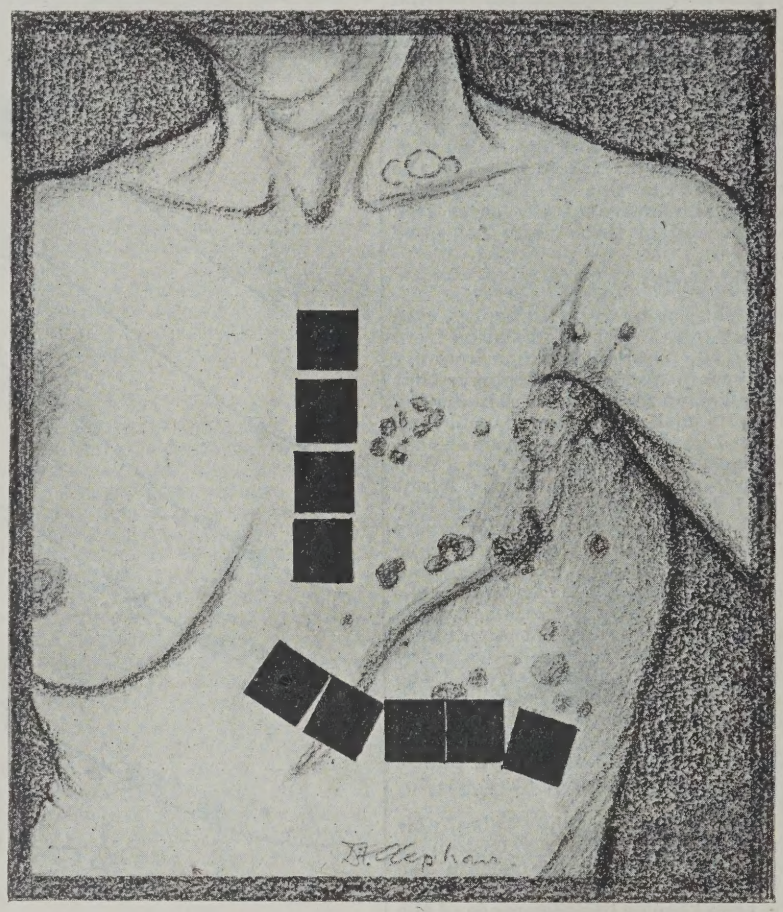
This case standing alone has only a suggestive value, though I could produce others in support of it. If a long incision into the subcutaneous tissue were made in an animal, and if carcinoma cells were planted along the incision in a line, as potatoes are planted in a trench, the application of a radium focus at one end

683550

of the incision should give information as to the stimulating or depressing effects of radiation expressible in exact mathematical terms. There has, I think, been a tendency to ignore the possible stimulating action of small doses of radiation, partly because of the absence of exact data with regard to it, partly because of the fear of exciting prejudice against a novel method of treatment. But the position of radiation in the treatment of malignant disease is now so unassailable that the second objection no longer holds. In any case to ignore difficulties is to perpetuate them.

If these provisional conclusions be accepted as facts I think there emerges a principle of great importance in the radiation treatment of malignant disease, whether by X rays or by radium—namely, that a careful endeavour should be made to delimit the area in which cancer cells are likely to be present, and that the periphery of the area thus marked out should first be treated. The treatment of the central part of the area should be reserved to the last. These remarks naturally refer to cases in which the whole area affected is too large to be treated at one sitting.

FIG. 2.



Radium barrage. 20 mg. capsule.

Take, for instance, a case of primary carcinoma of the breast. A circle of 10 or 12 in. with the growth as its centre may require to be irradiated. In my judgment the whole periphery of this circle should be treated before the palpable primary growth is submitted to the rays. The opposite, and, I believe, the usual practice is to irradiate the primary lump first and most, and so incur the risk of delivering a small stimulating dose to its microscopic extensions and driving them further afield. I make these suggestions with more confidence because in the field of radio-surgery I have tested this encirclement method and have found it to produce a great improvement in results. It deals effectively with the zone of microscopic infiltration and permeation. If, on the contrary, a central method of treatment is adopted this zone is stimulated to increased activity, and though the primary growth may disappear its dissemination is actually hastened.

In regard to diagnosis I wonder if radiologists take every opportunity open to them to verify their findings. Do they sufficiently study the pathology of the living (the phrase is from Sir Berkeley Moynihan's mint) as revealed in the operating theatre in cases which they have previously submitted to X ray examination? In connexion with this question I feel certain that the radiologist might with advantage oftener visit the wards and the operating theatre and the surgeon more frequently be found in the X ray room. Conference between colleagues is much better than the exchange of reports. Now that diagnosis and therapeutic radiology are both of them such large subjects it is worth considering whether the art of radiology would be advanced by a more complete separation between these two branches of practice.

THE STUDY OF RADIO-HISTOLOGY.

Surgery, like therapeutic radiology, is an art combating local disease by local measures, and there are some who believe that technique and manipulative skill are the sole necessary qualifications of the surgeon. This view has never held sway in England, for the founder of the English school of surgery, John Hunter, was an experimental pathologist who combined in himself the functions of the researcher and the surgeon. The Hunterian museum of the Royal College of Surgeons of England, a collection without rival in the world, is a standing witness to the belief of English surgeons that pathology is the real basis of successful surgery, and that technique is by comparison but its necessary handmaid.

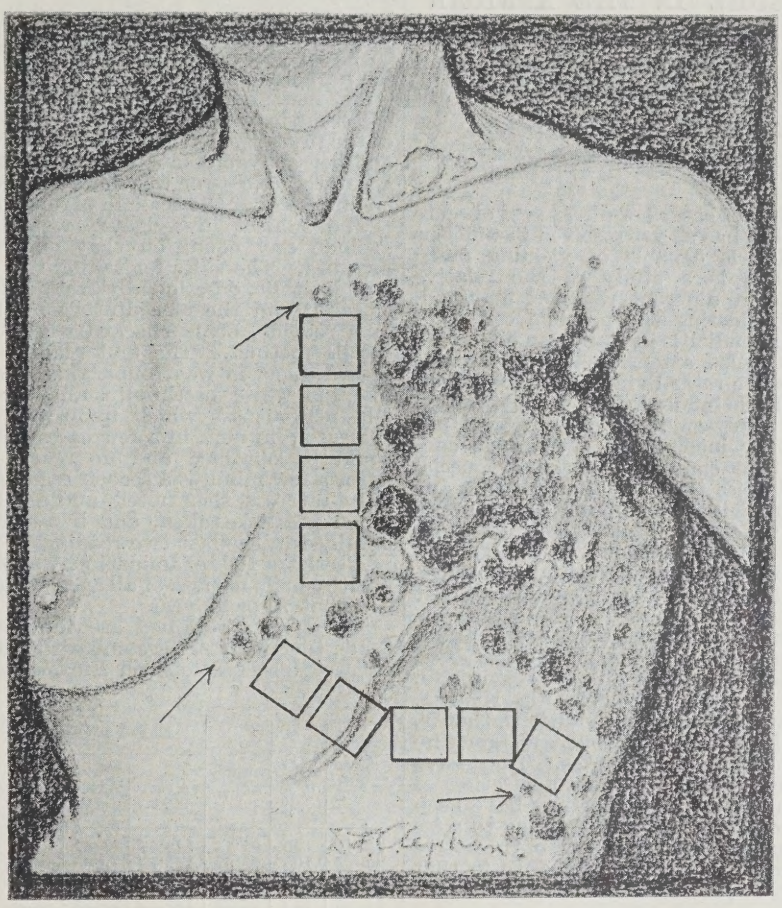
Now it appears to me that just as surgery may be led astray by the exclusive, I will not say the undue, exaltation of technique, so, too, may radiology. An intimate knowledge of the pathology of the conditions with which he deals is just as necessary for the radiologist as for the surgeon. Probably more than half the therapeutic work of radiologists is concerned with cancer. I feel certain that a closer personal study by radiologists in their earlier years of the way in which cancer spreads would increase the efficiency and success of its radiological treatment. This is all the more necessary if, as seems likely to happen in the near future, radiation largely replaces the knife in the treatment of cancer.

Radiologists, like surgeons, must attack their own special pathological problems, for the pathologist, with his illimitable field of research, generally considers pathological histology an exhausted area and is too busy to enter it. May I here suggest that the

universities of Cambridge and Liverpool, which have given such powerful aid to radiology by the institution of a diploma in the subject, and more recently by creating lectureships, should reconsider their syllabus so as to direct the attention of candidates more closely to those parts of pathology which bear upon radiology.

Correct and precise ideas on the mode of spread of cancer are vital to a therapeutic radiologist, and I may be allowed here to refer to my own work on the dissemination of breast cancer by permeation, which not only placed operative treatment upon a rational basis but has indicated also someconditions of successful radiological treatment. In a paper read in 1919 before the Electro-Therapeutic Section of the Royal Society of Medicine I tried to show how at that time some X ray treatment was vitiated by undue restriction and bad centring of the field of radiation, by exclusive attention to the lumps which could be seen and felt without regard to the microscopical extensions of the disease, and sometimes actually by failure to undress the patient and examine the tumour before its treatment was begun. This incursion of a surgeon outside his own territory was taken in the friendly spirit which inspired it.

FIG. 3.



Showing permeation round edges of barrage.

To illustrate what I mean I shall now draw attention to a few pathological observations which bear directly on the radiology of breast cancer. 1. In what appears to be the healthy region round a cancerous deposit there is probably a zone of microscopic infiltration, and outside this again a region of permeation, where the lymphatic vessels are choked by cancer cells. 2. Breast cancer invades the abdomen frequently by direct infiltration in the epigastric angle. 3. The glands along the internal mammary artery, which lie within the thoracic cavity, are invaded at about the same time as the axillary glands. 4. The plane in which external cancers spread is the plane of the deep fascia, because in that layer the main lymphatic plexus lies. Such cancers do not spread in the plane of the skin. 5. Tuberculous lupus, like cancer, is an invasion of the lymphatic system. It is not a skin disease but a lymphatic disease. The moral of these observations is too plain to need pointing. I may, however, remark that to cure either lupus or cancer an effective dose of radiation must not merely impinge upon the skin, but must be carried down at least to the plane of the deep fascia.

In order to illustrate the importance of correct pathological ideas in the field of practice, may I now describe an experiment which, with the patient's full consent, I carried out upon a case of recurrent breast cancer where numerous secondary nodules were spread over an area of the thoracic wall. In such cases X ray treatment directed to the visible and palpable nodules causes them to disappear, but the disease continues to spread and fresh nodules appear at the periphery. The reason, of course, is that beyond the remotest nodule there is a peripheral zone, lying in apparently healthy tissue, where the microscopic growing edge of the disease is spreading by permeation in the fascial lymphatic plexus. With the coöperation of Prof. Russ and of my registrar, Mr. Muir, a line of radium capsules, broken in the middle by an intentional gap, was laid down in the presumed situation of the microscopic growing edge over skin which appeared quite healthy and a maximal skin dose was administered. *No treatment was applied to any recognisable focus of disease.* Opposite the radium barrage the nodules ceased to spread, while they continued in the subsequent months to advance through the gap left in the radium barrage, and round its ends. Radiation had destroyed or inhibited the microscopic growing edge (Figs. 2 and 3). This experiment, which I have repeated since, is surely a proof that to see a cancer as it really is one must close the eyes and use the imagination (Figs. 1 and 2).

I venture to suggest that young radiologists should be encouraged to study the pathological side of radiology for themselves first by the establishment of a museum, in charge of a histologist whose opinion would in the course of years become of decisive value in radio-histological questions, and secondly by the establishment of one or more research scholarships in radio-histology. Now that the technical equipment of therapeutic radiology has reached such a high degree of power and accuracy, I am convinced that the nation which first places the subject upon a complete pathological foundation will lead the way to fresh triumphs. Now that radiology has come of age and

can control its powerful weapons, its future depends upon a closer study, from its own particular angle, of the diseases it has to fight, and of the tissue changes produced by radiation.

In conclusion, may I be allowed to express my personal thanks for help received to Dr. Douglas Webster and his staff at the Middlesex Hospital, and to many other radiologists from whom I have had friendly help and counsel.

BLOOD PRESSURE IN THE AFRICAN NATIVE.

ITS BEARING UPON THE ÆTIOLOGY OF HYPERPIESIA AND ARTERIO-SCLEROSIS.

By C. P. DONNISON, M.B., B.S. Lond.,
LATE MEDICAL OFFICER, EAST AFRICAN MEDICAL SERVICE.

In the investigation of causes of diseases of obscure ætiology, a factor that has as yet received insufficient attention, but which is capable of yielding much information of value, is a study of the relative incidence of disease in different races of mankind. For instance, in considering the possible causes of the prevalence of appendicitis in European countries, many writers have called attention to the rareness of this disease in native races living under conditions that have been but little influenced by the civilisation of white races.[1] The same statement has, not infrequently, but very incorrectly, been made concerning cancer. These comparisons are of special interest in those diseases that are alleged to be due to modes of living in civilised communities. A group of such diseases which occupies much attention nowadays are the allied conditions of hyperpiesia, arterio-sclerosis, and chronic interstitial nephritis, and it is to a consideration of these conditions that this paper is devoted.

The investigations recorded here were all carried out on natives living in one of the largest of the native reserves in Kenya Colony—namely, South Kavirondo, situated on the shores of Lake Victoria Nyanza. These natives live under primitive conditions, that is, under conditions which have probably undergone no appreciable change for many centuries. They have been but slightly influenced by the colonisation of Kenya, the main influences to which they have been subjected, government and missions, tending to raise the standard of the present mode of living of the native rather than to introduce any radical change in that mode.

Normal Blood Pressure in the African Native.

A consideration of the incidence of hyperpiesis amongst African natives entails, first of all, consideration of the normal blood pressure. Our knowledge of normal blood pressure at present rests upon figures chiefly gained from large numbers of records collected mainly in America.[2] It would be unwise to assume that the normal for an American citizen anxious to insure his life should also be the normal for an African native. Consequently a series of investigations upon apparently healthy natives was carried out. It is necessary, first of all, to place on record the conditions under which these investigations were made and the methods adopted.

The observations were carried out on the four main tribes occupying the South Kavirondo district—the Wakisii, Luo, Abakuria, and Abasuba. Men only were investigated. Recruits for labour in various parts of Kenya are examined in large numbers at Kisii Hospital, and these provided a large number of healthy young subjects for investigation. Older men were not so easy to procure at Kisii, but these were more readily obtained whilst on tour in the native reserves when the older men gathered together in council. It should be pointed out that the investigations at Kisii were carried out at an altitude of about 5700 feet, and, on tour, in country varying in altitude between 3500 and 5000 feet. It seems unlikely that such altitudes could have any marked influence upon the blood pressure of inhabitants.[3] Determination of the age of the natives was not easy. Natives rarely have any idea of their own ages, consequently their ages had usually to be estimated. No claim is made for strict accuracy with regard to the ages shown in the following table, but it can at least be claimed that they were grouped fairly correctly in relative age groups. It seems that it is uncommon for natives to reach what is called old age in the European. Occasionally natives were seen who seemed perhaps 70 to 80 years of age, but they were only met with infrequently. Consequently all natives judged to be 60 years of age or over were grouped together for purposes of calculation.

The instrument used was an aneroid sphygmomanometer made by Messrs. Down Bros. At the conclusion of the investigation the instrument was tested against another sphygmomanometer that was known to be accurate. No error was detected greater than 2 mm. on the parts of the scale in regular use.

The subject investigated was first examined to exclude any condition that might influence blood pressure. The rules for taking the readings, systolic and diastolic, described by Halls Dally, were followed closely,[4] and the auscultatory method was adopted as a routine, being checked where necessary by the tactile method. The first reading was always disregarded, as it was found that the African native, like his white brethren, suffers from apprehension and nervousness which frequently affect his blood pressure; in fact, in a few cases no constant reading could be obtained and no record could be made. After a few minutes a second reading was taken. The pulse-rate was then noted, and a third reading of the blood pressure taken, and if a constant figure was obtained in the last two readings a record was made.

A series of 1000 examinations was made in apparently healthy male natives of all ages, ranging from 15 years to about 70 or 80 years.

The results obtained are shown in the following table, with figures, for comparison, derived from large series of observations on Europeans and Americans.

Age group.	Cases examined.	Aver. pulse-rate.	Blood pressure.			Normal in Europeans and Americans.[2]		
			Aver. syst.	Aver. diast.	Aver. diff.	Syst.	Diast.	Diff.
15–19	99	68·71	123·07	81·89	41·18	123	80	43
20–24	100	63·22	122·76	79·99	42·77	125	81	44
25–29	100	63·57	126·37	83·96	42·41	126	82	44
30–34	115	64·55	126·05	84·73	41·31	127	83	44
35–39	100	69·46	125·55	85·86	39·69	128	84	44
40–44	93	68·52	118·32	81·29	37·03	129	85	44
45–49	96	69·17	113·19	75·50	37·69	131	86	45
50–54	100	72·20	109·79	74·09	35·70	133	87	46
55–59	100	70·73	106·59	69·63	36·96	135	88	47
60 and over	97	75·23	105·76	66·98	38·78	140+	90+	50+

Syst. = systolic; diast. = diastolic; diff. = differential.

It will be noted that the figures differ distinctly in the two races. Up to the fourth decade the figures for the two races agree approximately. After that the blood pressure, both systolic and diastolic, tends to come down in the African, whereas in the white races it continues its tendency to rise until the eighth decade.

Incidence of Hyperpiesia, Arterial Degeneration, and Chronic Nephritis.

The highest systolic blood pressure recorded during the course of the above investigation in a subject showing no pathological condition and no detectable signs of nervousness was 172 mm. This was observed to persist for about two hours, but unfortunately the case could not be followed up. Another case was found to be 150 mm., and this was observed to persist for two days. In nervous subjects it was not

uncommon to find a systolic blood pressure of over 200 mm. temporarily. It was very uncommon, however, to meet with a systolic blood pressure that persisted for long above 144 mm. Over two years at a native hospital, during which period approximately 1800 patients were admitted, afforded good opportunity for recognition of pathological conditions that might have arisen in the native population as a result of high blood pressure, arterial degeneration, and chronic nephritis, and where any suspected case was admitted blood pressure was recorded. No case of raised blood pressure was encountered, though abnormally low blood pressure was not uncommonly noted. On no occasion was a diagnosis of arterio-sclerosis or chronic interstitial nephritis made. One case was encountered that gave a history suggestive of angina pectoris, but no abnormality was detected on examination, and the blood pressure was 105/74. Occasionally cases of hemiplegia are seen amongst natives, but such as I have had the opportunity of examining have occurred in young men, have presented no cardiovascular abnormality, and circumstances have suggested that relapsing fever may have been the cause. Aortic incompetence has been occasionally recognised, but these cases have either occurred in young natives or have probably been of syphilitic origin. Hypertrophied hearts, without intrinsic cardiac disease to account for the enlargement, are very rarely met with in the African. Cases are sometimes met with in which the apex beat is displaced to the left, but after investigation of a number of these cases I arrived at the conclusion that the heart was displaced and not enlarged. There was no evidence of any myocardial inefficiency, and the blood pressure was invariably within normal limits.[5] Opportunities for carrying out post-mortem examinations have often occurred, and it has been noted that the native African usually shows much less atheroma in the aorta than does an average European of the same age. In a man of 30 frequently no signs of atheroma can be seen, and a man of 50 will often show slight traces only.

The results of this investigation thus lend support to the view that hyperpiesia and arterio-sclerosis are diseases associated with civilisation. Hyperpiesis has been recorded as quite common in Egypt by Ismail,[6] but this is a country that has been considerably influenced by European and other civilisations, recent and remote. Furthermore, Ismail points out that the disease is almost confined to middle, upper, and more educated classes, and is rare amongst hospital patients. It is of interest to record here that senile calcification of the aorta has been noted in the mummy of Meneptah (reputed Pharaoh of Egypt), and is to be seen in the museum of the Royal College of Surgeons.

Ætiology of Hyperpiesia.

Two main views of the causation of high blood pressure at present are described—namely, (1) the toxæmic theory, and (2) the view that the condition arises as the result of an over-responsive vaso-motor system, which has been described as the mental stress theory. Two sources of toxin have been stressed as possible causes of hyperpiesia and arterio-sclerosis—viz., (1) a focus of chronic infection, (2) derivatives of protein digestion. It is difficult to suggest forms of chronic infection that are common in Europeans and that are rare in the African native. Pyorrhœa is very common in natives under 30 years of age, and almost universal above that age. Tonsillitis is common, and nasal sinus infection is sometimes seen. Chronic ulcers of the leg are very common amongst them, and constitutional toxic effects due to them are frequently seen. Constipation is just as prevalent, I believe, as in England. Other conditions that are stated to be toxæmic in origin are common, as chronic arthritis and rheumatoid conditions. Meat is frequently consumed by the races in South Kavirondo, though possibly not to the extent that it is consumed in England. In this connexion some observations upon blood pressure in the Masai tribe, who feed largely on milk and ox blood, would be of interest.

The other view, of which one of the leading protagonists is Lord Dawson, is briefly that hyperpiesis is the result of a "high pressure existence" or of mental stress. I think almost everybody who has been closely associated with the African native will agree that he very rarely can be described as living a high pressure existence. McDowall[7] has suggested that the physiological rise in blood pressure that occurs as a result of mental stress is to provide for the increased muscular activity that should naturally follow occasions that create mental stress, but that under civilised conditions mental stress often fails to be followed by its physiological safety valve of muscular action. This view certainly receives support from the rarity of high blood pressure in the African native.

Comparison of Normal Blood Pressure in European and African Races.

Further allusion must be made to the differences between the normal blood pressures for the two races. Under the age of 40 years the figures for both systolic and diastolic blood pressures are very similar for the two races. Above that age the blood pressure for the European rises steadily up to the age of 80, after which it falls. The average blood pressure at 60 years of age is 140 systolic and 90 diastolic in the European, whereas in the African it is 105 and 67 respectively. The contrast is somewhat striking, and seems to require explanation. In both races there are, of course, fairly wide variations compatible with health, and figures of value can only be obtained by taking averages of large numbers. Systolic blood pressures of below 100 mm. are common in the African, and 110 were noted in the above observations. No less than seven cases were encountered of systolic blood pressures below 80 mm. in natives who appeared to be quite healthy. These natives were all considered to be 55 years of age or over.

Individual variations compatible with health are noted to occur in response to physical and psychical changes. Similarly, prolongation of, or constant repetition of, such stimuli has been suggested as being responsible for pathological changes. To apply these analogies to the racial variations it may be possible to evolve a hypothesis to account for such racial differences. The native African, or at least the type who lives in the native reserves, amongst whom these investigations were carried out, has probably for a large number of generations lived in a manner that has undergone but very slight change. The European and American populations have, on the other hand, seen revolutionary changes in their mode of living in a very few generations as a result of the industrial revolution of the nineteenth century, the increased facilities for travel and communication, the growth of large cities, and the increasing complexity of warfare. That such developments have had their effect upon the diseases of the race is undoubted. I suggest that such differences in the evolution of the two races could be held responsible for the differences in their normal standards of blood pressure; in other words, that the greater mental stress required by the ordinary European citizen in his everyday life, as a result of the tendencies of modern civilisation, has had its effect upon the physiology as well as the pathology of the race.

My thanks are due to Dr. J. L. Gilks, Director of Medical and Sanitary Services, Kenya Colony, for permission to publish this paper.

RADIUM THERAPY OF CANCER OF THE BUCCAL CAVITY.*

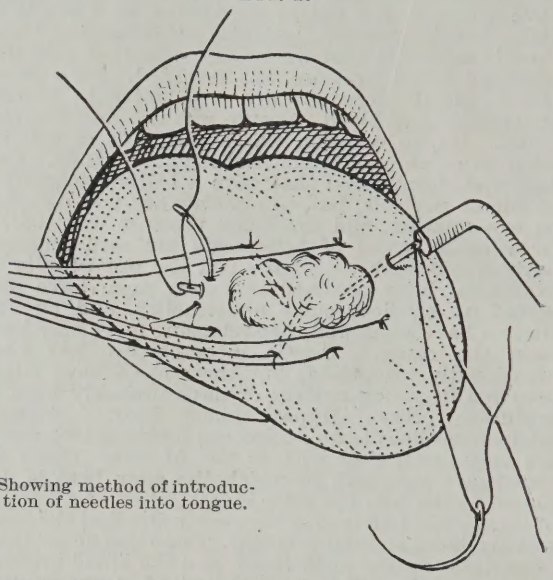
By STANFORD CADE, F.R.C.S. Eng.,
ASSISTANT SURGEON, WESTMINSTER HOSPITAL.

(With Coloured Plate.)

It is now established that primary cancer of the tongue can be made to disappear by means of radium in a large proportion of cases. Quick [1] in America, Regaud [2] in France, Ledoux [3] in Brussels have used this method of treatment well over five years, and the time is not far distant when statistics based on a minimum period of five years survival will be available in this country. The best results are obtained in early and operable cases—in these the disappearance of the growth depends upon a correct technique. In inoperable cases good results are obtained locally, although the problem of the extraoral extension of disease is still bristling with difficulties. Hopelessly advanced cases, so frequently sent for radium therapy, are beyond the stage where any form of treatment is of value, and to expect "cures" in this group of patients is at present to expect miracles. Radium treatment does not always result in a complete disappearance of the growth, and occasionally a local recurrence is seen two or three years after irradiation. In my experience a second treatment is possible and sometimes gives excellent results. Harmer [4] advocates diathermy excision of the scar left after irradiation. Radium treatment in careful hands often transforms an inoperable case into one suitable for operation.

Pathological Considerations.—The treatment of oral neoplasms by means of radium depends on the selective action of the gamma rays upon the newly developed cells. From the earliest days of radium therapy it was recognised that cells in mitosis were more sensitive to irradiation than cells at rest. But the success or failure of treatment does not depend solely upon the response of the cell to irradiation. It has been shown that the effect of irradiation on the stroma is equally important. Roussy [5] has shown that a good result may be expected in those cases where the disappearance of mitosis and cellular disintegration is unaccompanied by changes in the stroma. Personal observations on biopsies in cases of lingual cancer fully support Roussy's observations, and prognosis is bad in cases where the tissues are œdematous or scarred by previous fibrosis, due to so-called "precancerous changes."

Fig. 1.



Showing method of introduction of needles into tongue.

Whatever the mechanism of the action of radium on the growth, the effects of irradiation are partly dependent on the blood and lymph supply of the tissues, and the state of circulation in the irradiated part influences materially the results obtained from gamma ray therapy.

The tongue and oral cavity offer a field eminently suitable for close observation of the effects of irradiation on the growth, as the changes can be inspected daily. From continuous clinical observations in a series of 50 cases it is seen that between irradiation and the appearance of the changes a period of time elapses which varies with various factors. This "latent" period is of clinical importance, as both malignant cells and normal tissues, although apparently not affected at the end of treatment, are profoundly and permanently affected, the outward change not becoming apparent for a variable period of time.

There are four types of neoplasms commonly seen in the mouth: (1) the papillary, (2) the nodular, (3) the ulcerous, (4) the fissured. The degree of malignancy of these groups when considered from the point of view of "excisional" surgery is in the order mentioned. From the point of view of radium therapy the prognosis is reversed, and the papillary type, which is the most malignant, responds most rapidly to irradiation. The more rapidly the tumour grows the more sensitive it is to the effect of gamma rays. The sensitivity of tumours to irradiation can be increased by artificial means which are at present being investigated.

Anatomical Considerations.—Whatever the situation of the neoplasm its response to irradiation is the same. The results are better in the anterior group owing to the simplicity of technique in this situation. The posterior part of the tongue presents difficulties in approach and the extent of the lesion is easily underestimated. Growths of the inferior aspect of the tongue and floor of the mouth extend early beyond the intrinsic muscles of the tongue; they involve the alveolar margins and bone. This renders

Fig. 2.

Skiagram of mouth showing 14 platinum seeds in the posterior part of the tongue.

* Based on a paper read at the International Conference on Cancer, London, July, 1928.

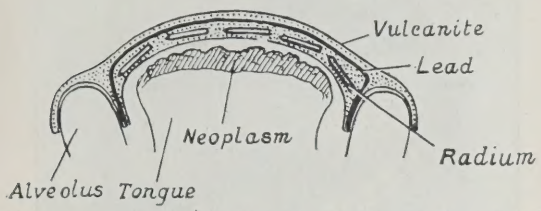
treatment difficult. Early lesions in the floor of the mouth give good results.

Methods of Irradiation.

The technique of irradiation varies with the anatomical site of the disease. Three methods of irradiation are used in the treatment of cancer of the buccal cavity.

1. *Interstitial Irradiation.*—This method consists in the introduction of radium salt or radon emanation

FIG. 3.



Method of surface application showing vulcanite apparatus containing radium. A lead lining protects the roof of the mouth and lower jaw.

screened by platinum into and around the tumour. It is most suitable for growths of small size and easily accessible to manipulation. The use of platinum needles is the method of choice in the treatment of lesions of the tongue and floor of the mouth. For tumours of small volume it is sufficient to surround the lesion with needles; if the lesion is extensive it is necessary to introduce the needles into the tumour as well. The advantages of this method in selected cases are (1) the possibility of calculating the dose carefully and accurately, (2) homogeneous irradiation, (3) prolongation of period of treatment, since normal tissues are protected by the multiplicity of foci and maximum screenage.

2. *Cavitary Method.*—This method is suitable for the treatment of cancer of the palate, uvula, certain

FIG. 4.

B, lead-lined vulcanite plate made from A. C, protection plate for lower jaw. D, plaster-cast of floor and side of mouth; the black area outlines the growth. E, plate made from D, carrying small box for irradiation. F, model made of stent, roofed with lead for surface application to tongue.

types of epitheliomata of the cheek and lip. A plate similar to a denture is used. This appliance is made for each individual case. It is made of vulcanite, stent, or composition, lined with lead, and carries the requisite amount of radium. The application may be continuous or interrupted, and is prolonged till the desired reaction is obtained. The palate and buccal aspect of the cheek are the only situations where this method is used in preference to interstitial irradiation.

3. *Surface Application.*—By surface application is meant the application of radium at a short distance from the skin. The distance at which the radium is placed varies with individual schools. At Westminster Hospital 15 mm. is the standard distance. The substance employed is known as Columbia paste.[6] Collars are made so as to cover the whole or part of the neck. This method is used for the treatment of secondary cervical deposits. The details of the preparation of the paste collars have been published elsewhere.[7]

Treatment.

The treatment of oral cancer is carried out in two or three stages. It consists in the treatment of the primary lesion by means of radium followed two or three weeks later by the treatment (surgical, radiological, or combined) of the lymphatic area. The reasons for adopting this method, which clinically give satisfactory results, are based upon the necessity of preserving the best possible blood and lymphatic

FIG. 5.

supply to the area treated. The disappearance of the tumour is hampered by the removal of lymphatics and ligation of blood-vessels, which, of course, is the object of the operation on the neck. This step therefore should be left till the primary growth has been successfully dealt with.

Primary Growth: Technique.

Tongue.—Before introducing radium it is necessary to carry out a scrupulous toilet of the mouth. Carious teeth are extracted, metal fillings removed, tartar scraped, and sepsis eliminated as much as possible. The introduction of radium needles is carried out under local or general anæsthesia according to the temperamental suitability of the patient for one or the other method; for lesions on the postero-dorsal aspect of the tongue, intratracheal anæsthesia through a nasal catheter is the method of choice. The growth is carefully examined and needles are introduced around it into healthy tissue at a minimum distance of 1 cm. from each other. The needles must be completely buried in the substance of the tongue, the linen thread only protruding at the surface, as otherwise small areas of necrosis occur around the protruding eye of the needle. The threads are passed through the substance of the tongue, tied at one end and cut short (Fig. 1). The long ends are collected into a rubber tube and attached to the skin of the cheek by means of strapping. The protection of the rest of the mouth, specially the palate and the alveoli, is obtained by means of dental plates lined with lead. When dealing with a neoplasm situated far back on the posterior aspect of the tongue, the introduction of needles may present serious technical difficulties. In this position platinum radon seeds are of great advantage (Fig. 2). Seeds are easily and quickly introduced and need not be sutured in. They can be placed and kept in position in situations inaccessible to needles. When platinum seeds are used in the mouth, no protection of the bony arches is required. But from the point of view of uniform intensity of

irradiation needles are superior to seeds. In cases where most of the tongue is involved by the disease and it is difficult to keep the needles in the tissues for the desired period of time, surface application by means of an intrabuccal apparatus is an alternative but less efficient method of applying radium (Figs. 3 and 4 (E)). The duration of surface application is 14 days.

Dosage.—Needles containing 0·6 mg. and 1·33 mg. of radium screened with 0·5 and 0·6 mm. of platinum are used. Their number varies with the extent of the growth. As a rule eight to ten needles are required. They are left in position seven to nine days. The total dose varies from 800 to 1600 mg. hours.

Pillars of Fauces and Uvula.—The method of choice is irradiation by means of radon seeds. The seeds are introduced by means of a trocar and cannula [8] round and behind the growth. Regular distribution is aimed at, the seeds being placed at a distance of 1 cm. from each other. The seeds have an initial strength of 1·8 or 1·2 millicurie each. Eight or ten seeds are necessary according to the extent of the lesion. They are left in position 10 to 14 days. The patient is examined every second day and the seeds removed when there is evidence of reaction manifested by redness and slight œdema. Hospitalisation is not essential, and the majority of cases can be treated as out-patients at this stage. If seeds are not available, small needles 9 mm. long containing 0·5 mg. of radium, screened by 0·5 mm. of platinum, are used; they must be securely sutured in position and this is facilitated by the use of cleft-palate needles. Protection of the hard palate and lower jaw is necessary owing to the continuous maximum intensity during the whole period of treatment. The needles are left in position seven days. The total dose is 1000 mg. hours.

Palate.—Intrabuccal surface application is the method of choice and is suitable for all cases except those involving the free border of the palate and uvula. A plaster cast of the roof of the mouth and the lesion is taken (Fig. 4 (A)). A vulcanite or stent apparatus is made and lined inside with 1·5 mm. of lead (Fig. 4 (B)); a window corresponding accurately to the extent of the lesion is cut in the upper surface of the plate; needles containing 2, 1·3, and 0·6 mg. of radium are placed

on the plate and covered with vulcanite; 15 mg. of radium are required. The plate is worn day and night for 10 to 14 days. It is removed daily and a mouth wash given. At the end of five days the needles are rearranged so as to obtain a more uniform irradiation. The results are satisfactory and extensive carcinomata involving nearly the whole palate have been made to disappear.

Buccal Mucosa.—Epithelioma of the cheek responds well to radium treatment. The extent of the growth is the main factor in the choice of the technique adopted. Surface application from inside the mouth or externally may be used as an alternative to needling in this situation and by this method there is less risk of perforation of the cheek and a more even distribution of radium is obtained. Needling with very small needles or seeds gives very good results. For a localised growth not involving the muscles of the face, a stent or shellac shield is made to fit either the lower or upper jaw whichever is most suitable for the individual case. A plate is attached to the apparatus so as to keep in contact with the neoplasm. The plate consists of a layer of lead 1·5 mm. thick, covered with stent, the radium is placed on the stent (Fig. 4 (D, E) and Fig. 5). The apparatus contains 10 mg. of radium and is worn for seven to ten days. Total dose: 2000–3000 mg. hours. If the growth has invaded the muscular layer of the cheek and there is difficulty in opening the mouth, external application by means of columbia paste is resorted to. The dosage in this case is increased to 5000 mg. hours.

Cervical Lymphatic Glands.

Operable Cases.—One month after irradiation of the primary growth, operative removal of the glands on the side of the lesion is carried out. The operation must be extensive and aim at the eradication of all the glands, deep fascia, sterno-mastoid muscle, and internal jugular vein—following Crile's technique. The removal of the sterno-mastoid simplifies the operation and gives a much better exposure of the glandular area. The removal of the internal jugular vein with all adjacent glands should be carried out from just above the clavicle up to the base of the skull or as near to it as practicable. All the glands removed must be individually examined histologically, and only in the absence of any deposits is no further treatment indicated. If one gland shows a secondary deposit, the neck must be irradiated.

Irradiation.—Three weeks after operation, when the wound is soundly healed, a Columbia paste collar 15 mm. thick is made. It covers both sides of the neck. An average of 70 mg. of radium is necessary. It is best to use needles of 1·3 or 2 mg. each. The operated side receives one third and the non-operated side two-thirds of the total quantity of radium. The average period of treatment is two weeks; the treatment is intermittent, the patient receiving 16 hours daily. The total dose is 10,000 mg. hours. This figure represents the dose emitted by the apparatus, and not the dose received by the patient. Erythema and superficial desquamation are the objective signs of sufficient dosage.

Inoperable Cases.—In cases where the mass of glands is fixed and involves the cellular tissues of the neck, complete surgical removal is impossible and radium therapy presents the only possible means of alleviating the patient. No case, however extensive the glandular involvement, should be left untreated. Bilateral irradiation is inadvisable in this group of cases. The reaction aimed at is severe and consists in complete peeling of the skin. It is important to irradiate the mass very slowly, and at least three weeks treatment is advised. The amount of radium varies with the size of the mass to be destroyed; 20–23 hours daily are given. The total dose amounts to 25,000–30,000 mg. hours. By this method good palliative results are obtained in cases where no other form of treatment is possible. As to permanency of these results, all that can be said at present is that patients have remained well up till two years after treatment, and when it is noted that these patients had large masses of glands and were inoperable, the results are encouraging.

It may be argued that if such results are obtained in inoperable cases, why not adopt this method in early cases and dispense with operation altogether? In the present stage of radium therapy the results are not sufficiently constant to justify this, and although palliation of symptoms and prolongation of life are obtained in inoperable cases, a combination of surgery and irradiation is still the best policy in operable cases.

Illustrative Cases.

The following five cases have been selected to illustrate the immediate results of radium treatment of cancer of the oral cavity. Case 3, one of the earliest cases treated, shows the result of bad technique, terminating in a radium burn. I am indebted to Dr. Braxton Hicks for all the histological and serological investigations in connexion with these cases, and to Mr. A. H. Clarkson for all the prosthetic work.

1. Mr. W. J., aged 50. Extensive carcinoma of the papillary type on the right side of the tongue and floor of mouth (see Coloured Plate, Fig. 6). There was a large mass of glands in the submental and submaxillary triangles. Biopsy: squamous-celled carcinoma. Treatment: 6 mg. of radium in 10 needles introduced around the growth and left in position seven days. Total dose: 1080 mg. hours. The primary lesion healed entirely (Coloured Plate, Fig. 7). Although the

SIR LENTHAL CHEATLE: LEGENDS TO ILLUSTRATIONS. (*See Plate opposite.*)

FIG. 1.—Whole section (natural size) of breast of woman, aged 32 years, who died in the seventh month of pregnancy. C = Nipple. B and B_1 = Active (genetic) growth of acini. A = Less active part from which Fig. 2 was drawn.

FIG. 2.—Section A from A, Fig. 1. Terminal ducts and acini in a lobule. The epithelium is in a state similar to that seen in mazoplasia. The pericanalicular and periacinous connective tissue has undergone hyperplasia. Among its fibres are seen many lymphocytes (compare with Fig. 3). B is the normal supporting connective tissue of the breast in which the lobule is embedded.

FIG. 4.—Section of breast. Terminal duct A_1 and A and its acini B, B_1. The duct ends and the acini begin about A where the elastica (unstained in this specimen) ends. The drawing represents a pure state of cystophorous hyperplasia. The shed colostrum-like cells in the transverse section of the duct A can be seen arising in all stages of formation from the epithelial hyperplasia within the wall of this duct. A collection of acini at B has become confluent and has formed an early cyst. Lining B_1 and B is the desquamative epithelial hyperplasia which is so typical of this state. In parts there is (unlike the hyperplasia in the duct) here and there a formation of small papillomata which are supported by delicate fibrillous stalks of connective tissue.

FIG. 5.—Section showing cystophorous hyperplasia in the groups of acini B where early cystic formation has begun. In the terminal duct A the epithelial hyperplasia is dysgenetic and strictly confined within distended but normal boundaries encircling the duct. There is a slight hyperplasia elastica which is not stained in this specimen. It is impossible to say how long the epithelial hyperplasia in the terminal duct will remain in its present state. It would be interesting to see this microscopical field at the end of about two years. There was no carcinoma of this gland. There were other parts of the same duct in which similar fields could be discovered.

FIG. 7.—A drawing of a part of a duct wall A from which has arisen a dysgenetic epithelial hyperplasia partly consisting of a papillomatous formation and partly sessile. B is placed in the lumen of the duct. The epithelial hyperplasia is still confined within distended but normal boundaries. The whole of a duct and its branches—of which this specimen is one—contained a similar dysgenetic epithelial hyperplasia. At one part epithelial cells had invaded outside structures and an early state of carcinoma existed. It was accidentally discovered in one of the whole sections that was cut and examined of this breast. There was no carcinoma in the lymphatic glands in the axilla which was cleared and examined microscopically.

FIG. 8.—Represents the two terminal branches A of a duct which has just divided (×30). The elastica is shown in this specimen and it has undergone enormous hyperplasia which also surrounds a few of the acini into which these two branches lead B and B_1. Dysgenetic epithelial hyperplasia of sessile type has taken place in the ducts and acini. Some of the epithelial cells have escaped into the surrounding connective tissue C and carcinoma therefore exists. Microscopical sections of the axillary lymphatic glands failed to reveal carcinoma.

glands were inoperable, a portion of the mass was removed, and a Columbia paste collar carrying 70 mg. of radium in 32 foci applied 18 hours daily for 18 days. Total dose: 22,600 mg. hours. The mass disappeared; there was extensive peeling of the skin of the neck. The patient died of cerebral hæmorrhage seven months after treatment; there was no local recurrence.

2. Mr. A. B., aged 56. Epithelioma of the tip of the tongue; on palpation a tumour the size of a walnut was felt in the anterior half of the tongue. The superficial ulcer involved the frenum; there was marked leucoplakia of the whole tongue (Coloured Plate, Fig. 8). Wassermann reaction: negative. Biopsy: squamous-celled carcinoma. Treatment: 8 mg. of radium in 8 needles introduced around and into the growth, and left in position seven days. Total dose: 1280 mg. hours. The tumour in the tongue disappeared; the ulcer healed. The leucoplakia was not affected (Coloured Plate, Fig. 9).

3. Mr. A. F., aged 60. Epithelioma of the palate. Early case suitable for radium treatment. The condition before treatment is shown in Fig. 10. An error of technique was committed and this had disastrous consequences. The needles used contained 5 mg. of radium each; the screenage was only 0·5 mm. of platinum. At present the needles employed for this type of lesion contain ten times less radium—viz., 0·5 mg.—and have the same protection. The total dose given was double the maximum dose: 4200 mg. hours. A radium burn resulted; the condition six weeks after treatment is shown in Fig. 11. The white slough took five months to separate, the adjacent portion of the palate was red and œdematous, the mouth was dry, there was intense pain. The patient died of exhaustion seven months after treatment.

4. Mr. H. H., aged 46. Very extensive ulcer on the left side and dorsum of the tongue (Coloured Plate, Fig. 12). No enlarged glands palpable in the neck. Biopsy: squamous-celled carcinoma. Wassermann reaction positive. Treatment: 6·6 mg. of radium in 11 needles inserted around growth and left in position seven days. Total dose: 1100 mg. hours. The condition three weeks after treatment is shown in Fig. 13 (Coloured Plate).

5. Mr. G. B., aged 53. Epithelioma of pillar of fauces, involving tonsil and extending to free edge of palate and uvula (Fig. 14). Enlarged glands on both sides of the neck. Biopsy: squamous-celled carcinoma. Treatment: 4·2 mg. of radium in seven needles introduced around and behind the lesion and left in position seven days. Total dose: 705 mg. hours. Complete cicatrisation of the lesion followed. The condition 5 weeks after treatment is shown in Fig. 15. A crile dissection was performed. This was followed by a radium collar.

ROYAL NORTHERN HOSPITAL.—The recent anonymous gift of £35,000 for the building of a pay-bed block of 60 beds was conditional upon a similar sum being contributed by the public to the general needs of the hospital by the end of the year. This sum has now been successfully raised.

WEST SURREY HOSPITAL LEAGUE.—This organisation, which was formed recently to manage the contributory scheme in connexion with the Royal Surrey County Hospital, has already achieved considerable success. There are between 13,000 and 14,000 contributors, and it is believed that a total of 40,000 can be reached.

DIET AND PEPTIC ULCERS IN CAVIES.

BY H. E. MAGEE, D.Sc. ABERD., M.B. BELF.,
W. ANDERSON, M.B. ABERD., F.R.C.S. ENG.,
AND
J. McCALLUM.

(*From the Rowett Research Institute, Aberdeen.*)

THE ætiology of peptic ulcers in man is still obscure, and any experiments which throw light on it are therefore desirable. The experiments reported in this paper were drawn up not only with this object in view, but also to study the effect of deficient diets on the rhythmical movements of the surviving intestine. The results, therefore, fell into two categories, pathological and physiological. The former alone are dealt with in this paper; the latter will appear in another journal.

Experiments.

The experiments were done on cavies which were three-quarters grown when they began. For the physiological work it was necessary to kill off from day to day the animals which showed well-marked signs of malnutrition. This could not have altered the pathological findings to any appreciable extent.

Preliminary Experiment.—In a preliminary experiment 15 cavies were divided into five groups of three each and fed as follows:—

1. Cereals with grass and turnips—control diet.
2. Cereals—deficient in inorganic elements, especially calcium, chlorine, and sodium.
3. Cereals + minerals—inorganic composition adjusted so as to be similar to that of No. 1 ration in so far as analyses were available.
4. Cereals + minerals—bases as in No. 3, but acid radicles (Cl, PO_4, and SO_4) in excess relative to No. 1.
5. Cereals + minerals—bases as in Nos. 3 and 4, but acid radicles as in No. 2, i.e., low acid-base ratio.

Rations 2 to 5 were also low in vitamins, especially A and D. They were undoubtedly deficient, because all the animals fed on them went downhill very rapidly, especially those in Groups 2 and 4. No. 4 ration was the most unsuitable; two of the animals died seven and ten days respectively after being placed on experiment. The other was killed on the seventh day. No. 5 ration was evidently the most suitable, because the two animals that died naturally lived much longer than any of the other experimental animals—viz., 22 and 24 days respectively.

Post Mortem.—Group 1: No abnormality seen. 2: Congestion on gastric and duodenal side of pyloric sphincter in three, and of the cæcum in the region of the ileo-cæcal valve in two. 3: In three, congestion with hæmorrhages into the mucosa round the ileo-cæcal valve. 4: Large liver abscess in one, pneumonia in two. 5: In three congestion in the region of the pyloric and ileo-cæcal sphincters, and in one of these a well-marked intussusception of the jejunum. This was very probably not agonal, because the animal was killed intentionally.

Sections were made of affected portions of the pyloric region, the adrenals, and other tissues. Out of five cases examined microscopically, two showed hæmorrhages and three others excessive vacuolation of the cortex of the adrenal. The congestion in the pyloric region involved chiefly the loose tissue on both sides of the muscularis mucosæ, but often the muscle tissue was involved. In places the epithelium of the villi or glands was degenerated and there was evidence of hæmorrhage into the lumen. Congestion was found in the thyroid, kidney, pituitary, and pancreas.

The pyloric lesions were very slight in Group 2, and in Group 4 the lesions found post mortem (pneumonia in two and liver abscess in one) were most probably secondary to the malnutrition established by the diet. These results are interesting in view of the fact that ration No. 4 was clearly the most unsuitable, while ration No. 2 came next. They suggested that a higher incidence of local lesions would be obtained by employing diets with a slight, rather than a marked, deficiency. In subsequent experiments, therefore, we attempted to postpone a fatal issue for as long as possible by incorporating small amounts of green food in the diets of some groups.

Expts. 1, 2, and 3.—Three other experiments were done. The diets are shown in Table I. The animals in Group 1 in each of the three experiments were controls; their diets were adequate because they all grew normally and remained healthy. The animals in Groups 2 and 3 in each of the three experiments deteriorated from the start, and after a variable time developed signs of malnutrition. All the animals were given as much of their particular ration as they cared to eat, except that in Group 2, Expts. 1 and 2, green stuff was given in the amounts stated to each animal per day. No. 2 rations were all poor in calcium, sodium, and chlorine, and also in vitamins A and D. No. 3 ration was relatively poor in potassium and in vitamins A, C, and D. All the experimental rations were rich in phosphorus.

In view of the changes in the adrenals a number of unilateral-adrenalectomised cavies was included in all groups in Experiments 2 and 3. The left gland was removed in every case, because of the great operative difficulties in removing the right. Contrary to Sharpey-Schafer's statement (1924, p. 100) we were convinced that the deaths of the very few animals that succumbed could be attributed to some complication, avoidable or accidental, during the operation and not to removal of the gland per se. Autopsies were done on all animals, generally within an hour after death, whether natural or not, except on those that died during the night when several hours elapsed before examination was made. Sections were made of affected parts of the stomach and duodenum, the adrenals, and the thyroid.

Results.

In none of the non-operated control animals was any significant organic change observed. Sections of tissues from 15 of these were examined. The findings in the other groups are summarised in Table II.

TABLE II.

* In only six cases did circulatory disturbances occur along with abnormal vacuolation (three in Expt. 2 "N.," two in Expt. 3., "N.," and one in Expt. III., "Op.")

Operated Controls.—In the control groups there were eight unilateral adrenalectomised animals. Three of these showed congestion and hæmorrhage and three others excessive vacuolation of the adrenal cortex. Three of these six had numerous ecchymoses in the gastric mucosa, which were obviously not due to injury of the viscus during operation.

Experimental Animals: Alimentary Canal.—The congestive changes in the pyloric region were as described under the preliminary experiment. The erosions varied very much in degree. In one case an ulcer of the hepatic aspect of the duodenum had perforated, but the resulting abscess was localised. In the remainder the appearances varied from cases where only the surface epithelium was destroyed to others where only one layer of infiltrated muscle separated the lumen from the peritoneum. The superficial lesions were extensive and evidently acute; congestion, hæmorrhages, and degeneration of mucous membrane were their predominating features. The deeper lesions were more localised, but less congested than the superficial. Discrete ulcers with cellular infiltration of the surrounding tissues were the most conspicuous appearances in the subacute lesions, which were generally found only in the most long-lived animals. The ulcers varied in size from a speck, just visible, to a more or less circular area about 5 mm. in diameter. The edges were sloping and not punched out. In several cases, whether erosions or ulcers were present or not, the gastric and duodenal mucous membrane was unhealthy looking and peeled off very readily.

Without exception, animals that had lesions of the stomach or duodenum showed evidence of stasis in the cæcum and proximal colon, whether or not inflammation was present in these places. In some cases the cæcum was overloaded and atonic-looking, in others it was markedly sacculated. In both types the distal colon was generally contracted and cord-like, often containing bloody fæcal matter and casts. Variable amounts of foul-smelling gas were often present in cæcum and colon. Constipation was the rule in the late stages, but diarrhœa was frequent in the early stages, especially in Group 3.

Adrenals.—The changes in the adrenals were like those observed by McCarrison (1921, p. 170) except that the hæmorrhages were not confined to the periphery of the cortex, but occurred all over it, sometimes bordering on the medulla. The increased vacuolation was not confined to any particular zone, although in individual cases one zone was often more affected than others. Very often the entire cortex was involved. In normal animals vacuolation, when at all conspicuous, was confined for the most part to the zona glomerulosa. One may reasonably assume, in agreement with Cramer (1926), that the hyperæmia was evidence of increased activity of the gland and the hæmorrhage of excessive activity. The significance of the abnormal vacuolation was not so clear, and our procedure did not throw any direct light upon its nature—whether it was genuine and due to degenerative changes, or apparent and due to accumulation of lipoid which had been dissolved out by the balsam in which the sections were mounted (Cramer, 1918). This author regards the presence of cortical lipoid as a sign of functional activity and its absence as a sign of inhibition or exhaustion of the cortex, which, he suggests, is concerned in the secretion of adrenalin. The excessive vacuolation in our experiments appeared to be merely an exaggeration of the normal, and the regular outlines suggested vesicles full of non-staining material rather than degenerative changes. We are inclined to think, therefore, that the vacuolation was a sign of great activity, a view which is supported by the results in our own adrenalectomised controls and by the observation of Bast, Supernaw, and others (1928). They have recently found increased vacuolation of the cortex in rabbits subjected to prolonged nervous and physical stimulation. It is, therefore, probable that the conditions observed in the adrenals were indications of great or excessive functional activity.

Thyroid.—In the thyroid the only abnormal condition we could be sure about was hyperæmia of very varying degrees. In some cases the vesicles were small with scanty colloid and cubical epithelium (signs of activity); in others the vesicles were large and full of colloid and the epithelium was flattened (signs of diminished function). These conditions were probably not related to the deficient diets, because thyroids from normal animals showed much the same appearances. Changes in the histology of the thyroid have,

however, been observed as a result of deficient diets—Sharpey-Schafer (1924); Harris and Smith (1928); Murray (1923).

Discussion.

The disordered rhythm (as found in our physiological experiments), the alimentary stasis, the lesions in stomach, duodenum, and large bowel, and the changes in the adrenal are apparently all interrelated and caused either proximately or remotely by the deficient diets. A priori one would expect dysfunction of the bowel movements to be primary to the organic lesions. The fact that irregular rhythm was obtained in some cases showing little or no visible organic change strengthens this belief. The disorganised movements would presumably lead to stasis followed by putrefactive changes evoking abnormal sensory stimuli. These, in accordance with Carlson's opinion (1916), would induce pylorospasm, and in consequence hyperæmia of the parts and delayed emptying of the stomach. The signs and symptoms referable to the alimentary canal, observed in completely adrenalectomised animals by Biedl, Elliott, Vincent, and others, and more recently by Rogoff and Stewart, Swingle, and his colleagues, and others, point to a definite connexion between the function of the adrenals and of the alimentary canal. Rogoff and Stewart (1926, *a*) almost invariably found circulatory disturbances in the alimentary canal post mortem and often erosions or ulcers in the stomach or duodenum. They found the highest incidence of ulcers (7 out of 17 dogs) in adrenalectomised pregnant females, whose survival period was always many times longer than that of males or non-pregnant females. Rogoff and Stewart (1926, *b*), Banting and Gairns (1926) have also found similar ulcers in adrenalectomised dogs. Furthermore, Hartman (1924) has cited experiments by Weiskotten, who found hyperæmia and hæmorrhage of the adrenal cortex in patients dying from superficial burns. In such cases, as is well known, peptic ulcers of an acute type are common.

Cramer (1926) has suggested that products derived from intestinal putrefaction cause stimulation of the adrenals, an opinion which leads to consideration of the action of protein decomposition products—e.g., histamine on the adrenals. We are not aware of any experiments bearing directly on this point, but it has been shown by Dale (1920) and confirmed by Banting and Gairns (1926) and by Crivellari (1927) that the resistance of completely adrenalectomised animals to histamine is abnormally low. Dale has pointed out that a close similarity exists between the condition of the blood in adrenalectomised animals (lowered plasma content) and animals that have received large doses of histamine. The increased concentration of the cellular and of other constituents of the blood after adrenalectomy has been confirmed by Rogoff and Stewart (1926, *c*), Swingle (1926), and Hartman et al. (1927). The evidence, therefore, strongly suggests that the function of the adrenals is to antagonise the action of histamine and probably of similarly constituted substances. Furthermore, it is interesting to note that McIlroy (1928) has recently produced peptic ulcers in cats by large injections of histamine with and without previous local experimental trauma. These considerations have led us to think that excessive intestinal putrefaction is causally related to spasm of the pylorus and to adrenal exhaustion, and that the latter, as well as the former, is a factor in the production of circulatory disturbances in the stomach and duodenum. If acute these conditions apparently cause death without any marked degenerative change; if subacute they apparently cause ulceration of a chronic type. Ulcers in the pyloric region or congestive or degenerative changes have been observed by Rowlands (1927), and by Underhill and Mendel (1927) as well as by McCarrison, as a result of diets deficient in various vitamins. It would seem, therefore, that deficiency of vitamins was the factor of greatest importance in the production of the lesions found in these experiments. The deficient diets used by us, however, were badly balanced in regard to several important inorganic constituents as well as being poor in vitamins. It is fairly certain also that many of McCarrison's diets, which induced organic changes in the pyloric region in cavies and monkeys, were poor in inorganic elements. It is therefore unwise to attribute the lesions observed by us to one or other of these factors only.

As these experiments proceeded we became more and more convinced of our inability to interpret the significance of many of the results obtained, especially those of a physiological nature. We therefore felt it desirable to postpone work on the effects of inadequate diets until our knowledge of the fundamental characteristics of smooth muscle was sufficiently far advanced to permit of more precise inferences. The experiments published here are therefore somewhat incomplete, but it is hoped that they will throw some light on the problem they were planned to elucidate. We fully realise, however, that derangements of other functions or of other tissues, not considered in this paper, probably also contribute towards the production of peptic ulcers.

SEVERE ANÆMIA OF PREGNANCY AND THE PUERPERIUM.

WITH A REPORT OF TWO CASES.

BY WILLIAM EVANS, M.D., M.R.C.P. LOND.,

MEDICAL FIRST ASSISTANT AND REGISTRAR, THE LONDON HOSPITAL.

INVESTIGATION of the records of 1913 labours conducted at Queen Charlotte's Maternity Hospital in 1926 and of 2170 labours in 1927 failed to disclose a single case of severe anæmia of pregnancy and the puerperium. Reference to the literature also proves that the disease is uncommon. These facts alone render unnecessary any apology for placing the present cases on record.

The condition was first described in 1842 by Channing,[1] an American obstetrician, who distinguished it from anæmia resulting from hæmorrhage. He reported ten cases, all terminating fatally. Osler [2] classified the severe anæmias of pregnancy and the puerperium under four headings: (1) anæmia from post-partum hæmorrhage, (2) the severe anæmia of pregnancy, (3) post-partum anæmia, and (4) the acute anæmia of post-partum sepsis. He considered the anæmia in groups (2) and (3) to be the result of hæmolytic agents produced in the changed metabolism of pregnancy or in the katabolism of the post-partum state. Rowland,[3] reporting two cases in America, assumed that a syncytial hæmolysin is produced in the ectodermal cells of the chorion during pregnancy, and that later an antihæmolysin is found in the maternal blood; failure in the formation of this substance results in persistent anæmia. Smith [4] in America recorded eight cases. He considered adminis-

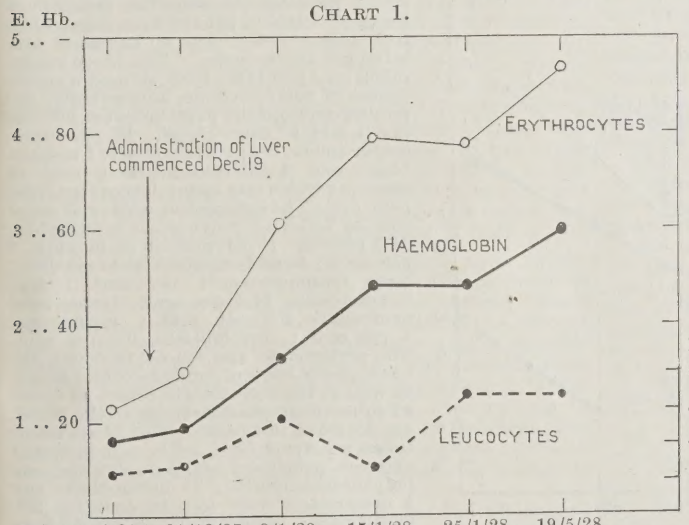
tration of dilute hydrochloric acid to be of distinct value in the treatment, and its deficiency to be a probable ætiological factor. In 1925 Larrabee,[5] of Boston, cited 17 cases. The blood picture in eight resembled that found in pernicious anæmia, in seven it simulated a secondary anæmia, in one it was atypical, and in another the condition resembled aplastic anæmia. He suggested achlorhydria as the main ætiological factor. Hoskin and Ceiriog-Cadle [6] reported a case which closely simulated Addisonian anæmia. They regarded as predisposing factors achlorhydria and general debility before pregnancy. Neale [7] in this country reported two cases in 1927. In one of them sepsis of the cervix uteri was present. Murdock,[8] in a paper recording two cases, pointed out that little or nothing was known of the ætiology of the disease. McSwiney [9] in India studied the condition in 43 patients. He found that it occurred in 1·69 per cent. of all pregnancies and is much commoner in early than in late pregnancies. The maternal mortality was 35 per cent. and the fœtal mortality 56 per cent. Multiple pregnancy, which occurred in three cases, he considered to be amongst the predisposing causes. The Wassermann reaction proved to be positive in eight cases out of 20—i.e., 40 per cent. Balfour,[10] reporting 150 cases investigated at the Bombay Clinic, found the disease more prevalent amongst Mohammedan than Hindu women. The illness usually commenced between the sixth and seventh month of pregnancy and was ushered in by fever, with or without diarrhœa. Enlargement of the spleen was detected clinically in 18 per cent. of cases. Albuminuria was common.

The Two Cases Described.

CASE 1, aged 29, was admitted to the London Hospital on Dec. 15th, 1927, under the care of Dr. Theodore Thompson.

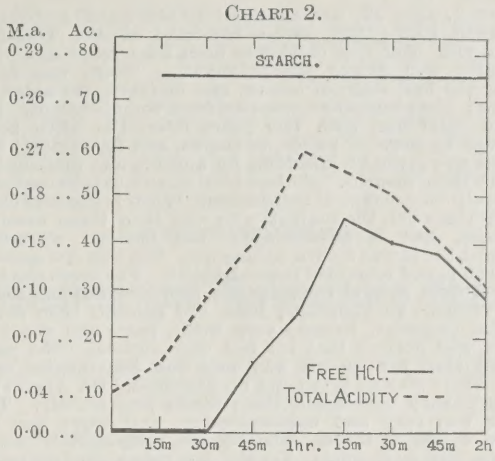
History.—The birth of her first child eight years previously occasioned no trouble. She remained well during the second pregnancy, which resulted in the birth of a full-term baby weighing 8½ lb. There was no excessive bleeding and no laceration of the perineum. The first child was then 15 months old. Immediately after delivery she complained of pallor, shortness of breath, great weakness, and swelling of the feet. She gradually got better. Three years ago, during the latter half of her third pregnancy, she complained of extreme and increasing pallor, great weakness, and shortness of breath. There was no fever nor diarrhœa. and the feet were only slightly swollen. The labour was uncomplicated, a full-term child was born, and the patient again gradually improved. During the second month of her fourth pregnancy she complained of weakness, shortness of breath, swelling of the feet and legs, palpitation, and increasing pallor; her friends remarked that she was "yellow." There was never any fever, diarrhœa, or vomiting. The symptoms progressed until the eighth month, when the onset of premature labour terminated the pregnancy. There was no excessive bleeding and the perineum remained intact. The symptoms persisted and she applied for admission to hospital one month after confinement. All four children were said to be healthy and thriving.

CHART 1.



Indicating progress in Case 1, as shown by successive blood counts.
E. = Erythrocytes per c.mm. in millions.
Hb. = Percentage value of hæmoglobin.
L. = Leucocytes per c.mm. in thousands.

CHART 2.



Record of gastric acidity values in Case 2, as determined by analysis of the fractional test-meal.
M.a. = Percentage of mineral acid calculated as HCl.
Ac. = Acidity of 100 c.cm. in terms of c.cm. N/10 HCl.

On examination the patient, a moderately well-nourished woman, appeared very weak, tired, and hardly able to move. She was extremely pallid, the skin being a deep buff colour. The mucous membranes were pale but jaundice was absent. There was no dental sepsis; the tongue was slightly furred. Temperature ranged from 97° to 99° F., and the pulse was of normal rate and rhythm. The blood pressure was 125/80. A hæmic murmur was heard in the pulmonary area. Examination of the lungs and central nervous system disclosed no abnormality. Retinoscopy proved the fundi oculi to be normal. The spleen was easily felt during deep inspiration; the liver was not enlarged. There was gross œdema of the feet and legs. The pelvic organs were normal and there was no vaginal discharge. A trace of albumin was found in the urine, but at subsequent examinations it was clear. There was no evidence of hæmorrhoids. The Wassermann reaction in the blood-serum was negative. The Ewald test-meal demonstrated absence of free hydrochloric acid, the total acidity value being 8. The fractional test-meal also demonstrated achlorhydria throughout. There was no abnormal fragility of the red blood corpuscles. Van den Bergh's test gave a negative direct reaction; the indirect reaction was weakly positive, showing presence of 0·7 mg. of bilirubin per 100 c.cm., equivalent to 1·4 units. There was slight excess of urobilinogen in the urine. The blood, tested for hæmolysis and agglutination, was found to belong to Group 2. The blood count taken on Dec. 15th, 1927, showed poikilocytosis and anisocytosis; erythrocytes, 1,200,000 per c.mm.; hæmoglobin, 16 per cent.; colour-index, 0·57; leucocytes, 2640 per c.mm. The differential white cell count showed: polynuclear neutrophils, 70·5 per cent.; polynuclear eosinophils, 3 per cent.; large hyaline cells, 3 per cent.; small lymphocytes, 19·5 per cent.; large lymphocytes, 3·5 per cent.; coarsely granular basophilic cells, 0·5 per cent.

Treatment.—Blood transfusion was considered inadvisable. An iron mixture was prescribed and daily injections of sodium cacodylate, gr. ½, were given. On the fourth day after admission liver treatment was commenced. This consisted of ½ lb. of fresh liver, finely minced, to which had been added orange juice and sherry. This preparation was given twice a day. Her condition rapidly improved and she was feeling well when she left hospital on Jan. 26th, 1928. She was next seen on May 19th, 1928, when there had been no recurrence of symptoms and she appeared in normal

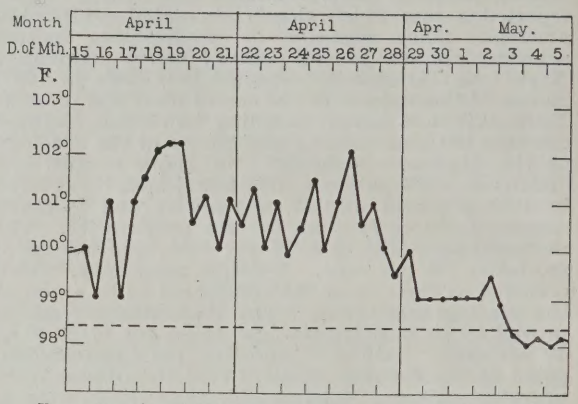
health. There was no œdema of the feet, but the spleen still remained easily palpable on deep inspiration. A blood count showed slight poikilocytosis and anisocytosis; erythrocytes, 4,700,000 per c.mm.; hæmoglobin, 60 per cent.; colour-index, 0·64; leucocytes, 6800 per c.mm. The patient was last seen on Sept. 8th, 1928, and appeared quite well. The intermediate blood counts in this case are recorded in Chart 1.

CASE 2, aged 32, was admitted to the London Hospital on April 15th, 1928, under the care of Dr. Theodore Thompson. Her first child was born nine years ago. She remained well during the pregnancy. There was delay during the first stage of labour, and delivery was aided by forceps; the puerperium was free from complications. Her second child was born two years later, the birth being followed by onset of pallor, weakness, and flatulence. The patient was given 25 injections for anæmia and remained in bed for three months. She had been unable to take medicine by mouth on account of indigestion. When her second child was 5 years old, the patient, who was then three months' pregnant, had a miscarriage; the medical attendant informed her it was a twin pregnancy. She was not anæmic at the time and remained in good health. For years she had suffered from painful hæmorrhoids, but bleeding had never been severe. In February, 1928, the patient, then seven months' pregnant, became very weak, pale, and short of breath, and noticed that her feet were swollen. She complained that her mouth was dry and her tongue very sore. There was no fever and no diarrhœa. On April 8th, the pregnancy terminated three weeks prematurely. The labour was easy and uncomplicated, and there was no excessive loss of blood. She became progressively worse and was sent to hospital. On the day before admission she had epistaxis, which was easily controlled. The three children had remained well and healthy.

On examination the patient was drowsy and apathetic, and when roused spoke or muttered incoherently, her cerebration being slow and her speech deliberate and often disconnected. Her respiration (28 per minute) was sighing in character and accompanied by conspicuous movement of the alæ nasi. She was extremely pallid and profoundly anæmic; her lips were almost colourless. The skin was of a deep buff colour. There was intense pallor of the mucous membranes but no jaundice.

Temperature was 100° F. on admission and during the first three weeks in hospital there was continuous or remittent pyrexia (see Chart 4). The tongue was dry and furred; the teeth showed no sepsis. The pulse (110 per minute) was regular and of fair volume, and the blood pressure was 130/90. A hæmic murmur was heard in the pulmonary area. There was gross œdema of the feet and legs. The fundus uteri reached to the upper border of the os pubis. The spleen was not felt. No abnormal physical signs were found in the lungs and the central nervous system. Retinoscopy showed normal fundi. The lochial discharge was normal in amount and colour, but offensive. On vaginal examination the uterus was found to be slightly enlarged, a finding consistent with the presence of some degree of subinvolution. Rectal examination revealed external and internal hæmorrhoids; there was no bleeding. A catheter specimen of urine was acid, with a specific gravity of 1015, and contained a trace of albumin and no sugar. A small deposit consisted of a few red cells, leucocytes, and epithelial cells; there were no casts present; culture grew *Staphylococcus albus*. There was no diarrhœa and the stools were normal.

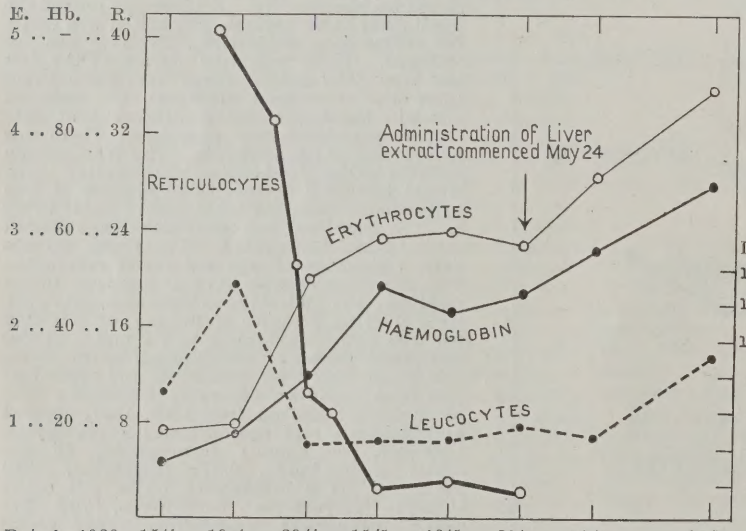
CHART 4.



Recording the temperature in Case 2 during the first three weeks in hospital.

The Wassermann reaction in the blood-serum was negative. The blood-serum calcium was found to be 9·2 mg. per 100 c.cm. The blood culture was sterile. The fractional test-meal (see Chart 2) demonstrated the presence of free hydrochloric acid in normal concentration in the gastric contents. The blood, tested for hæmolysis and agglutination, was found to belong to Group 4. Hæmolysis of the red cells ceased at 0·5 per cent. concentration of sodium chloride. The van den Bergh test gave a negative direct reaction; the indirect reaction was feebly positive, showing the presence of 1 mg. of bilirubin per 100 c.cm., equivalent to 2 units. There was no excess of urobilinogen in the urine. The blood count, taken on April 15th, 1928, showed a severe degree of poikilocytosis, anisocytosis, and polychromatophilia; erythrocytes, 900,000 per c.mm.; hæmoglobin, 12 per cent; colour-index, 0·7; 1 normoblast, 1 megaloblast, and 3 microblasts were seen in counting 200 white cells; leucocytes, 7000 per c.mm. The differential white cell count was as follows: polynuclear neutrophils, 61·5 per cent.; polynuclear eosinophils, 2 per cent.; small lymphocytes, 14 per cent.; large lymphocytes, 1 per cent.; large hyaline cells, 11·5 per cent.; transitional neutrophils, 2·5 per cent.; myelocytes, 7 per cent.; myeloblasts, 0·5 per cent. The erythrocyte and leucocyte count, the hæmoglobin content, and the colour-index, as well as the reticulocyte count, as found at subsequent examinations of the blood, are recorded in Chart 3. The blood count taken on April 19th, 1928, demonstrated extreme poikilocytosis, anisocytosis, and polychromatophilia; 24 normoblasts and 4 microblasts were seen in counting 200 white cells; myelocytes and myeloblasts were also present. In subsequent blood counts no primitive red cells nor white cells were seen.

CHART 3.



Illustrating progress in Case 2, as shown by successive blood counts.
E. = Erythrocytes per c.mm. in millions.
Hb. = Percentage value of hæmoglobin.
R. = ,, ,, ,, reticulocytes.
L. = Leucocytes per c.mm. in thousands.

Treatment.—On April 15th the patient was given liver prepared in the same way as that given in Case 1, but she vomited after each administration. Two days later a preparation of liver extract was given, but this also induced vomiting and was discontinued. As in Case 1, blood transfusion was considered dangerous in view of the grave degree of anæmia. The patient, however, made fair progress on general treatment, as shown by Chart 3. From April 29th to May 20th her condition remained stationary, and it was on the latter date that liver extract

(Boots), one phial twice a day—i.e., equivalent to 1 lb. of raw liver daily—was given and tolerated. The result was most favourable, the patient making a rapid and uninterrupted recovery. Re-examined on July 25th she appeared in perfect health and had remained free of symptoms. The same good progress had been maintained when she was last seen, on Sept. 8th, 1928.

Observations and Conclusions.

As in pernicious anæmia, so also in the severe anæmia occurring during pregnancy and the puerperium, the true ætiology of the condition still remains obscure. That achylorhydria is a prominent ætiological factor is not borne out by Case 2, as the fractional test-meal showed free hydrochloric acid in the gastric contents in normal concentration (see Chart 2). It is known [11] [12] that in anæmia following hæmorrhage or due to some other cause, a state of achlorhydria may be established as a secondary factor, being the result rather than the cause of the anæmia. Similarly the absence of free hydrochloric acid in Case 1 may have resulted from the severe anæmia present at the two previous confinements. The theory that the condition is due to syphilis cannot be seriously entertained; in neither of the cases reported here was there any history of syphilis, and the Wassermann reaction was negative in both. That there exists in patients suffering from the disease a natural predisposition to anæmia is difficult to dispute; but inquiry into the past history of the present cases proved that from childhood onwards they had both been perfectly healthy and had never previously suffered from anæmia.

The condition simulates Addisonian anæmia in many respects; thus in both instances there may be a great reduction in the erythrocytes, the presence of primitive red cells, an increase in the reticulocyte count, the presence of slight splenic enlargement, and finally the beneficial response to liver therapy. In both conditions, also, the established anæmia appears to be primarily dependent on the failure of the primitive cells in the bone-marrow to differentiate into the mature erythrocytes. Abnormal metabolites formed during the disturbed metabolism of pregnancy would appear to be the cause of the failure in the condition considered here. In cases reported in the literature a deposit of free iron was discovered in the various organs at autopsy. Investigations of the two cases reported here fail to give evidence of the existence of a hæmolytic agent. Jaundice was absent in both cases, and the van den Bergh indirect reaction was only very feebly positive. There was only a very slight excess of urobilinogen in the urine in Case 1 and no excess in Case 2. It will be noted that in both instances the hæmoglobin content was very markedly reduced. Hæmorrhage and sepsis are excluded as possible ætiological factors in both cases.

Each case illustrates how the anæmia, once established, tends to recur in later pregnancies, anæmia of a severe degree being present at the second, third, and fourth confinements in Case 1, and in the second and fourth in Case 2, both patients remaining well between the attacks. Furthermore, the anæmia may become more pronounced and its onset earlier during each successive pregnancy. Both patients were young, and the anæmia in each case followed the birth of the second child. When the anæmia becomes established during pregnancy, premature labour is the rule.

Although many cases recorded in the literature have terminated fatally, the prognosis is good, the disease having a natural tendency to recovery after parturition. Furthermore, as this investigation has established, the outlook is greatly improved by the immediate beneficial response to liver therapy. Charts 1 and 3 indicate the good progress made by both patients after the administration of liver. With such a remedy in our hands it becomes important to recognise this rare condition in its initial stages and to commence treatment before the onset of labour.

I am greatly indebted to Dr. Theodore Thompson for permission to publish the cases, and to Dr. P. N. Panton, Director of the Hale Clinical Laboratory, for the various tests employed in the investigation of both patients. I wish also to thank Dr. E. G. Frewer for his help in the investigations.

Clinical and Laboratory Notes.

FOUR CASES OF APPENDICITIS SIMULATING OTHER DISEASES.

BY DR. CHARLES FLANDIN, D.S.O.,

MÉDECIN DES HÔPITAUX DE PARIS: HON. PHYSICIAN TO THE HERTFORD BRITISH HOSPITAL, PARIS;

AND

J. CAMPBELL GILROY, M.B. EDIN.,

RESIDENT MEDICAL OFFICER TO THE HOSPITAL.

SINCE the days when appendicitis was termed typhlitis or perityphlitis, and treated medically, great advance has been made in our knowledge of this condition. It is extremely seldom now that cases of acute appendicitis are left undiagnosed until their chances of recovery have been gravely prejudiced. Cases of subacute appendicitis with recurring attacks of colic are also usually operated on before they can become the cause of any considerable lasting damage to health. Nevertheless, the appendix can prove a most subtle and deceptive adversary, disguising itself under the symptoms of some other complaint, or causing symptoms so slight that they do not alarm the patient and often cause no great worry to the practitioner, unless he has made a very searching examination.

The pitfall of mistaking a subacute appendix, with recurring attacks and intervals of quiescence, for a duodenal ulcer is now generally appreciated and guarded against, but even yet it often happens that a chronic appendix in its later stages is erroneously diagnosed as tuberculosis, cancer, or some other wasting disease. A chronic appendix of long standing can cause as marked a cachexia as tuberculosis or a neoplasm, and it is very doubtful whether we diagnose it often enough during this phase. This is because the main complaint is often of weakness, lassitude, and loss of weight, and it is frequently only after a very searching inquiry that we learn that the patient has suffered from a "weak digestion" for a long time. This paper is based on cases seen at the Hertford British Hospital during the past six months. We are reporting four of the most striking cases which were sent to hospital wrongly diagnosed, but we have seen several others which, although correctly diagnosed when sent to hospital, had been treated for a considerable time—two of them for years—as other entirely different diseases.

CASE 1.—A woman, aged 28, was sent up to the out-patients' department with a diagnosis of cancer of the large intestine. For five days before admission she had vomited after every meal, the vomit being sour and copious. She had no definite pain anywhere, but suffered from a dull, heavy, uneasy feeling in the region of the umbilicus. She had never had a good digestion, and could remember being subject to attacks of vomiting even as a girl at school. As far as she could remember, this vomiting had never been

accompanied by any marked pain, but she often suffered from indigestion after meals. Four or five years ago she had been diagnosed as a pernicious anæmia, but a blood-film later disproved this. Her indigestion had become worse during the last two years, and eight months before admission she had been confined, since when she had been losing weight rapidly. She was very constipated and had been so for many years.

On examination she was anæmic and very cachectic, with sallow and putty-coloured skin. Her mouth was very sore, with small ulcers all over its mucous surface; the tongue was dry, furred, and extremely sore. The temperature was 97° F., the pulse-rate 120, and the pulse was soft and running. The subcutaneous fat had nearly all disappeared from the abdomen and the skin had lost practically all its elasticity. No tumour, apart from fæces in the descending colon, could be found. There was generalised abdominal tenderness on deep pressure, and over McBurney's point this tenderness was especially marked. The muscular resistance of the lower part of the right rectus was increased. An olive oil enema produced a good result, both flatus and large, hard constipated scybalæ being passed. The heart sounds were weak and of a fœtal rhythm; there was a hæmic murmur and pulsations in the neck. The white blood count was 15,000, and a test-meal revealed no free hydrochloric acid in the stomach. The patient was very toxic and it was impossible to undertake any operation until the general condition, and especially the state of the heart muscle, had been improved. She had been suffering from cardiac attacks for three weeks before admission, and two days after her arrival she died from syncope.

Post-mortem Findings.—Autopsy revealed a chronically inflamed appendix about 6½ inches long, with many adhesions between it and the cæcum. It was patent throughout its length and contained four small concretions. There was no neoplasm in the abdomen or pelvis. The kidneys showed microscopic chronic interstitial changes. The liver was in a state of fatty degeneration. The heart valves were competent but the microscope revealed much fibrous tissue in the musculature. The cause of death was obviously a severe toxæmia due to chronic appendicitis, the final stage being toxic myocarditis and heart failure.

According to her history this appendix had remained undiagnosed for a considerable number of years, probably since she was a girl at school. Indigestion had thus come to be an accepted feature of her life, and she did not think it worth while to consult a doctor about it. When she finally did ask advice about her general health too much importance was apparently attached to her general symptoms and not enough to her local ones, with the result that the possibility of an appendix was overlooked, and first pernicious anæmia and later cancer was suspected. Her confinement eight months before admission had overtaxed her already undermined health. It was the proverbial "last straw." She lost weight rapidly, had a constant uneasiness in the epigastrium, vomited after meals, and was so constipated that fæcal lumps in the large intestine could be felt through the abdominal wall. She had the cachectic sallow look so commonly associated with neoplasms, and superficially the clinical picture was very much like that of cancer.

There were, however, indications of a chronic appendix rather than of a malignant tumour. The long unbroken history of digestive disturbance is rather against cancer, for she began to have trouble about 15 years before admission and did not markedly lose weight until after her confinement. Again, she was rather young for cancer, although, of course, cancer cannot be ruled out by age. The leucocytosis (15,000), the quick soft running pulse, the definite tenderness over McBurney's point, and the increased muscular resistance in the right iliac fossa, pointed clearly to a chronic appendix, and these signs must have been there, waiting to be recognised, for some time.

CASE 2.—A young woman, aged 29, sent in as a pulmonary tuberculosis, complained of cough, with much sputum, lassitude, sleeplessness, headaches, and lack of energy. She had always been delicate, even as a child, and had lately become extremely nervous. She volunteered no further information, but closer questioning revealed that she had suffered from "biliousness" since her youth, and when she started work she adopted the unhealthy and irregular dietary which is unhappily all too common among typists. Her lunch consisted of tea and buns at a café, and when she returned at night she was usually too tired to bother to prepare a meal, and contented herself with more tea and some bread and cheese. Her sleep was very disturbed and she awoke in the morning unrefreshed, drank a cup of coffee, ate a roll, and went to the office, thus completing the vicious cycle. She was habitually constipated, and at times complained of severe pains around the umbilicus and in the right iliac fossa. Lately she had developed night sweats and a cough with scanty frothy sputum. For the past two months she had suffered from amenorrhœa. She had had heart trouble due to rheumatic fever since she was a child. She went to a doctor who diagnosed tuberculosis and sent her to hospital.

She was painfully thin and very anæmic. Her tongue was furred, her breath fœtid, and her teeth bad. Her temperature was 98·2° and her pulse-rate 110 per minute. Her chest expanded equally on both sides; there were coarse crepitant râles in both bases, but no dullness on percussion. Nothing else abnormal was found. There was a double mitral murmur. The white blood count was 22,000. X ray showed the usual marling at the bases, common in all city dwellers, but nothing else abnormal. No tubercle bacilli were found in three examinations of the sputum. There was marked diminution of subcutaneous abdominal fat, and loss of elasticity of the skin. On palpation we found slight generalised tenderness over the whole abdomen, slightly more marked over McBurney's point. The muscular resistance of the right rectus was slightly increased. Per rectum there was no tenderness. After she had been in hospital two days she developed an unmistakeable attack of appendicular colic. The urine contained albumin.

It was first of all necessary to treat the bronchitis, which cleared up in four days. Operation revealed a large, red, retro-cæcal appendix, covered with white flaky deposits of lymph. There were many firm adhesions between the appendix and cæcum. The lumen was patent throughout its length, the mucous membrane being very swollen and unhealthy. There was a large concretion at its tip.

Since operation the patient has never complained of any more pain in the stomach, her cough has never returned, and she has put on weight. Her teeth have been attended to, her dietary corrected, her colitis is being treated, and she is feeling much better. She does not get so tired, though her heart still causes her distress when she over-exerts herself.

In cases which present symptoms very similar to those of tuberculosis, but without any characteristic signs or X ray appearances, it is, we think, prudent to bear the appendix in mind and thoroughly interrogate and examine the patient. In this case, as in the majority, the mistake in diagnosis was due to incomplete examination. Without close questioning she did not mention her digestive symptoms, and without these the case certainly resembled pulmonary tuberculosis. However, after the bronchitis had yielded to treatment we were left with nothing abnormal in the chest, and while under observation she had an attack of appendicular colic, so that the diagnosis was made clear.

CASE 3.—A man, aged 34, sent in as a duodenal ulcer, had been ill for two years before admission. He suffered from intermittent attacks of boring pain in the epigastrium. The pain radiated through to the back. The interval between the attacks was originally two or three months, but for two months the pain had been continuous and woke the patient from sleep. It came on about an hour after each meal and continued until the next. He never vomited though he had suffered from nausea, which had become worse. Diet at first relieved the pain, but later failed to do so. There was no history of melæna, waterbrash, regurgitation of acid, or a bad taste in the mouth, but the patient suffered continually from flatulence. He was slightly constipated and had lost weight. During the preceding year he had been diagnosed as a duodenal ulcer and dieted; he improved, but became worse again immediately the treatment was stopped.

He was very thin and had a gastric expression. His teeth were good. His tongue was moist and lightly covered with white fur. The abdominal wall was very muscular, but subcutaneous fat had largely disappeared from under the skin. There was marked tenderness in the epigastrium in the mid-line, just under the costal angle, and slight tenderness over McBurney's point, but none over the gall-bladder or per rectum. The liver was not enlarged. The urine contained bile for three days after admission. X ray of the stomach showed a stenosis at the pylorus, and an irregularity in the outline of the greater curvature; the latter we attributed to gas. The meal was rapidly evacuated from the stomach and small intestines, and was all in the lower coils of the ilium and the cæcum in four hours. He was kept on large doses of belladonna for one week and

then X rayed again; the same stenosis of the pylorus was present, but there was no irregularity in the greater curvature.

The diagnosis lay between a pyloric ulcer and a subacute appendix, and therefore at operation we employed a right lateral incision, which enabled us to examine both these organs. The stomach was found to be absolutely normal, but the appendix was retro-cæcal, and very congested and inflamed. It was removed and found to contain a large concretion. Since the operation (five months) the patient has had no more illness.

Sir Berkeley Moynihan [1] has said:—

"More mistakes are made in a diagnosis of gastric ulcer than is the case in any other abdominal disorder. The stomach is an organ full of sympathy for other sufferers, and it speaks so loudly that its voice only is heard. We cannot rid the matter of error until we realise how very difficult the diagnosis of gastric ulcer really is, and until we decide that, no matter how confident the clinical diagnosis may be before operation, it shall not guide us during the operation too firmly."

The possibility that this case was an appendix was appreciated, but the radiographic appearances and the clinical picture kept the diagnosis in doubt right up to the time when the abdomen was opened. It would be well if, before a definite diagnosis is made of gastric or pyloric ulcer—comparatively rare complaints—the commoner abdominal disturbances, such as appendicitis and cholecystitis, were always excluded.

CASE 4.—A man, aged 57, had been treated for neurasthenia in various nursing homes for over four years before admission, and on one occasion had undergone Weir Mitchell treatment for three months. He complained of a "depression in the stomach which flew to his head." Questioning revealed that by the word "depression" he meant "a pain which left him weak." This affected him at any time and bore no relation to meals, although certain highly spiced or very rich meats would bring it on. He never vomited during these attacks of pain and had not lost weight. Lately he had become afraid of people, even members of his own family, because he thought they would upset his temper and thus cause his pain. He had been very constipated for many years. He had been unable to concentrate on his work, and had suffered from sleeplessness and bad dreams.

He was a well-nourished man, not of the nervous type. His temperature was 98° and his pulse-rate 79. His tongue was furred, but his teeth were good. Nothing abnormal was found in the chest. There was plenty of subcutaneous fat on the abdomen. The patient was very defensive, and a good deal of persuasion was required before we could examine him. He was definitely tender over McBurney's point and there was increased muscular resistance on the right side. The white blood count was 26,000, and nothing abnormal was found in the urine. A bismuth meal revealed nothing abnormal, but on palpation under the screen it was seen that the tenderness was localised to a definite point in the cæcum (presumably the root of the appendix).

At operation a long, patent, chronically inflamed appendix was removed. There were many adhesions between it and the cæcum. When opened it was seen to contain very thick mucus mixed with fæcal particles; the mucous membrane was œdematous and unhealthy.

Since operation (three months ago) the patient has complained of no more pain and no more nervous symptoms. He is being kept on a diet for his colitis.

The diagnosis of neurasthenia in this case must have been due to failure to make a complete and careful examination. The patient had many neurasthenic symptoms but a chronic appendix was the beginning of his trouble. He was not, however, the type of man to accept indigestion as an everyday feature of his life. He had never had it before the age of 53, and, as prolonged treatment failed to cure it, the pain "got on his nerves." He would wait for it and live in daily dread of it. It is worthy of note that if a man of 50 complains of persistent indigestion for the first time in his life, it is very seldom that no organic cause can be found, and neurasthenia should be the last diagnosis. Before any man, young or old, is treated as a nervous dyspepsia the appendix should be absolutely excluded. A white blood count is often very helpful in pointing to the existence of inflammation, and it is probably not done often enough.

All these cases emphasise the need of a thorough and careful examination of every patient, no matter how trivial his complaint may seem. First impressions, though lasting, are not always correct; therefore let us avoid them.

REMARKS ON COLONIC LAVAGE.

BY VIOLET M. H. RENDALL, M.R.C.S., L.R.C.P. LOND.,
LATE CLINICAL ASSISTANT, SAMARITAN HOSPITAL FOR DISEASES OF WOMEN; CLINICAL ASSISTANT, GORDON HOSPITAL FOR RECTAL DISEASES.

A YEAR ago Dr. Chalmers Watson and Dr. P. De made a communication to THE LANCET [1] entitled Unrecognised Toxic Substances in Human Fæces. This paper, which was stated to be frankly provocative, was read before the Medico-Chirurgical Society of Edinburgh, when Dr. Watson invited commentary from practitioners whose independent observations of facts brought under their notice, he said, would be useful. Thus encouraged, I venture to publish some notes upon colonic lavage in particular relation to Dr. Watson's remarks upon the more than occasional confusion among medical men and nurses as to what may constitute normal fæces and what the evidence may be of an elementary toxæmia. His reflections here are practically concerned with colonic lavage, and during the 12 months that have elapsed since Dr. Watson's paper was read in Edinburgh I have taken notes of certain patients and have also availed myself of opportunities to see the technique employed at various centres.

Colonic lavage as a means of treatment, and to some extent as a means of diagnosis, is becoming more employed in this country—that is common knowledge; and if it is not used so extensively as in America and in Germany, that is perhaps partly because the treatment is with us very often left in the hands of unqualified persons who are not all equally capable of understanding either the reasons for the procedure or the results of the lavage. There have been articles written in lay and semi-medical publications in this country which have described the procedure. These articles have sometimes gone so far as to attribute to conditions of the large intestine the degenerative changes which are associated in a natural way with old age; consequently that big proportion of the population that wishes to stay youthful has concluded that any method of removing toxic waste products from the bowel and changing the intestinal flora may meet their object. The result has been that in this country colonic irrigation has run a risk of not taking its right place in scientific procedure, while—and this is serious—the treatment is administered too often by unqualified people whose results may easily fail to give satisfaction, and so discredit the procedure. Especially is this so because the lay agent almost naturally regards the washing out of the colon as the whole treatment of the case, whereas it is only a mechanical aid to general therapeutics. It is not profitable to send a patient suffering from auto-intoxication or even constipation to have lavage now and again, for while general symptoms may thus be relieved the cause of the condition will not be removed. This will be known to the qualified practitioner, and will be discovered by the patient, but many who administer lavage will consider that with a temporary relief success has been achieved. When the treatment is administered upon qualified advice precautions will be taken to see that there is no source of sepsis in teeth and mouth, pharynx, tonsils, or nasal channels, which would provide a continuance of the infection. Cases which had already been submitted to lavage I have found to remain substantially unaltered because the conditions of the intestinal

[1] THE LANCET, 1928, i., 174.

flora have not been recognised, and no attempt has been made to meet them by diet and acidophilous therapy.

Indications.

Colonic lavage is described in text-books, especially American ones, in sections upon the treatment of chronic constipation, and in such cases, although it does good to remove stale fæces, permanent improvement is not established by merely emptying the colon. The cause of the constipation must be ascertained, the proper diet arrived at by trial and expert massage, and graduated abdominal exercises must accompany the treatment. It is hardly too much to say that the most important part of a colonic irrigation treatment is usually the accompanying massage, for only through massage can the general tone of the colon be improved, while from the patient's point of view this measure has the advantage that they can be taught to massage themselves, a procedure that would usually only occupy some 20 minutes every morning. Colonic irrigation with accompanying massage, and instruction about exercise, will be of value only if the removal of any septic foci that can be detected is insisted upon. Then the following common conditions, perpetual headache, "biliousness," flatulence, and many signs of indigestion and constipation will be removed, but the lavage must be employed in the right way and at the right time. The same may be said in regard to many forms of colitis and many manifestations of so-called rheumatism, of gout, sciatica, and neuritis, things which were mentioned by certain of the speakers at the conference this summer in Bath on Rheumatic Diseases and put forward by Sir George Newman in his Presidential Address.[2] In Germany, in so-called rheumatic cases, where the discovery of the septic focus is in question, it is usual to examine the results of a lavage to ascertain how far the intestine may be mechanically at fault, the procedure not excluding bacteriological examination. These cases make up a large group in a general medical practice; in many of them temporary relief will be obtained promptly by lavage, but if permanent removal of the disability is to follow treatment considerable general care of the patient must accompany the procedure. In more serious diseases colonic lavage can only be looked at in the light of a general health measure. Many mental conditions, and some forms of asthma, may derive great temporary benefit in this way, and particularly in certain subjects lavage of the colon makes a difference to the sense of well-being that may manifest itself in circumstances of physical or mental strain; but I am not advocating the use of what properly employed is an important therapeutic measure as a temporary dope. On the other hand, of those who might say that to recommend as a general health measure a procedure that is not natural—namely, washing out of the colon—I would ask how many people in crowded communities or taking part in the usual social intercourse of to-day do lead natural lives?

Method.

Since the publication of Dr. Watson's paper I have looked into various methods of colonic irrigation that are commonly employed, and it is clear that they vary so much that the amount of benefit obtained from them must vary also. Visits were paid to various health resorts—Plombières, Harrogate, and Bath among them—and at clinics every opportunity was given to me of observing the technique. The quantity of fluid used was not constant, the amount ranging from one to as much as five or six pints; the sterilisation of apparatus was more carefully attended to at home than abroad; the rapidity with which injections were given was very different in different clinics; nor was the height of the containing cylinder determined by any fixed rule. The variations I could understand to be right, but only if the reasons for them could be seen to be related to particular cases. My own procedure, unless a practitioner in charge of the case desires me to vary it, or unless there are other and particular indications, is to give a quarter of an hour's massage and two douches of two and a half pints each, with variations of the douche to suit the requirements of the case.

I wish to advance the following points: (1) Colonic lavage should be done under the direct supervision of a qualified practitioner. (2) The amount of fluid used must vary according to the capacity of the patient, and the fluid should be used as slowly as possible to avoid dilating the colon, but to make any fixed rules in the matter is wrong. (3) The actual fluid used can be varied according to the symptoms of the patient—there are stimulating and there are soothing douches which can be employed in accordance with the conditions. (4) The value of colonic lavage is not obtained when it is only employed as a temporary measure, and by itself, to relieve some symptoms that are often self-diagnosed. Its real value is seen when it forms part of a general treatment in connexion with massage and appropriate diet, and when it is directed upon medical lines towards definite therapeutic objects.

SUBMUCOUS INJECTION OF HÆMORRHOIDS WITH QUININE UREA HYDROCHLORIDE.

BY CHRISTOPHER HOWARD, M.R.C.S. ENG.

THIS method of treating hæmorrhoids was brought before the medical profession at large by the publication, in France, of an article[1] by Dr. Bensaude, of L'Hôpital St. Antoine, Paris. Bensaude had been working on this method since 1921, and had therefore had very considerable experience before he published the details. At the time of writing the article he had tried his method on some 4000 cases. The number has now reached nearly 5000, and the method is still unassailable from the point of view of accidents or serious complications. With the exception of minor differences of technique and the difference in the solution used, the procedure is not unlike that advocated by Mr. A. S. Morley in this country. The use of quinine urea hydrochloride has, I think, one definite advantage over oily solutions of drugs that will produce sclerosis in that it has a local anæsthetic action and is not only absolutely painless but relieves any rectal pain that may have been present when the patient presented himself for treatment. An outstanding advantage of the treatment is its rapidity. Watching Dr. Bensaude work in the out-patient clinic is apt to cause astonishment at the speed and facility with which large numbers of cases are treated. In the private consulting-room, of necessity, the operation takes longer, but even when the procedure is a strictly one-man operation the whole thing can be carried out in ten minutes to a quarter of an hour.

Having watched Bensaude and being convinced of the tremendous value of this work, I started it some six months ago, and think that the experience gained may be worth attention, although it is limited.

Apparatus.

The solution used is a 5 per cent. solution of quinine urea hydrochloride. This is put up in 5 c.cm. ampoules, and keeps indefinitely; it does not need a large needle as it has not the viscosity of vehicles such as oil or glycerine. A proctoscope is necessary, but no particular model is indispensable—the simpler the better. Bensaude uses his own model, which has a long handle so that the hand which is controlling the instrument does not impede the vision. It also has a bevelled edge which, by the introduction of the obturator, can be turned round the full circle, bringing into view whichever arc of the rectum is desired. The best syringe is a 5 c.cm. model with an extension, made by Collin. It has two semi-circular extensions under which the index and middle finger of the hand can slide, and this enables the operator to control the point of the instrument with accuracy and to get a fair idea of the amount of pressure needed to drive the fluid through the needle. To the nozzle of this syringe is attached an extension about 4 inches long, and on the end of this, by an ordinary press-on joint, is fitted a 1 cm. platinum needle. It is

[1] Bensaude, R., and Cury, P.: Presse Méd., 1928, xxxvi., 706.

essential to use platinum because the ordinary steel needles affect the solution and cause precipitation and consequent blocking of the lumen. Platinum is excellent in every way, for it does not have this effect on the solution; it remains sharp for a long time; it is easily sterilised, and is very unlikely to snap. The long extension is necessary because in some cases of marked varicosity the vein may extend up the rectum as far as Houston's valve, and the injection may have to be made as far up as this. The only other necessities are two or three stick-swabs. These should be firm and strong so that, if necessary, exudate of the fluid through the puncture hole made by the needle can be controlled.

I am convinced that the most important requisite, apart from the essentials already mentioned, is a good light, for the whole object is to place the solution between the vein and the mucous membrane of the rectum and not in the vein itself. When working alone I find the best lamp is one made by Davidson, which by an arrangement of lenses throws a very good, even light, concentrated in a beam which fills the bore of the proctoscope, and so throws very few shadows. A high voltage lamp, situated over one's shoulder, has advantages, but, though admittedly it gives a strong light, there is too much play of reflection from the shining surface of the proctoscope lining, and consequently visibility is impaired.

Perhaps the most important part of the operation is absolute sterility. When dealing with a highly septic area, such as the anal canal, there is a temptation to be careless.

It might be justifiable to recall a case which occurred some little time ago, which is impressive, and which will act as a reminder that great care is necessary. In this particular patient a spreading ulcerative colitis supervened on pile injection with a carbolic solution in oil, which was followed by sloughing, septic absorption, and death. At the post-mortem examination it appeared evident that the lesion originated in the injected pile, and, though probably the resistance of the patient at the time of the injection was very low, that does not lessen the importance of the argument in favour of a careful technique.

As an antiseptic solution, the French tincture of iodine is the most suitable. It does not sting the patient and is stronger than the tincture of other countries.

Operative Procedure.

The instruments required—that is to say, the various portions of the syringe, the proctoscope, the obturator, and the swab-holder—are all taken direct from the steriliser just long enough to give them time to cool before they are actually needed. Gloves are always worn, and a finger-stall is placed over the index finger of the glove to make the preliminary examination before the injection is given. Where an extensive digital examination is necessary in a new patient seen for the first time it is as well to change the gloves after the examination. Plenty of lubricant is necessary for the painless introduction of the proctoscope, and K.Y. jelly is the best. This is slightly antiseptic and not greasy, a point which anyone who has ruined clothes or carpets with greasy lubricants will much appreciate. For examination the genu-pectoral position is undoubtedly the best, but for treatment the left lateral is to be recommended. The patient feels a slight prick as the needle enters the mucous membrane, and most people can bear pain better lying down than in an awkward position such as the knee-elbow. Furthermore, in the nervous type of patient, one has to remember that one is dealing with a highly sensitive area, and better relaxation is obtained if the patient is lying down.

When the anuscope is inserted with the light focused up the tube it will be possible to see in great detail any pile-bearing area in the rectum. One makes a mental note of the position where the piles are most obvious, and then carefully traces them up until no further sign of the varicosity can be observed. Just before this point is reached is the point where the first injection should be made. Successful treatment depends entirely on finding this position and on making the injection around the vein, and not in it or through it. It is rather difficult at first to control the end of the needle, as the needle with the extension is such a long one. Attempts to control the tremor of the hand by taking thought usually result in increased tremor; however, in a short time the speed attained will do away with this.

When one has decided where to make the first injection a stick swab is pushed up, soaked in iodine, and the area carefully swabbed. The injection is then made, the amount given being sufficient to produce a definite wheal under the mucous membrane. Recognition of the point at which a sufficient quantity of fluid has been injected depends on the sense of definite resistance to the plunger of the syringe transmitted to the thumb. It is only by practice that some sort of constant can be obtained, but this is undoubtedly the best guide to correct dosage. The striæ produced, which have elsewhere been advocated as the signs of correct dosage, are of little value, because their appearance and intensity depend on other factors besides the submucous pressure—factors such as the condition of the mucous membrane and the amount of distension of the rectum.

Most patients do not complain of any pain and the prick of the needle often passes unnoticed. If the patient should complain of pain it is usually a sign that the needle has not been put in correctly and has been plunged too deeply or too shallowly. In the latter case the mucous membrane is being forcibly stretched and a considerable amount of pain is produced.

After the injection has been made and the pressure on the piston of the syringe has reached the point at which the needle is withdrawn, the proctoscope is drawn down the rectum and another injection is made, again swabbing the area, below the original injection. It is seldom necessary to give more than 3 c.cm. at any one sitting, and it is useless to try to hurry things by injecting too much. If one created three large bullæ by the injection of quantities of the quinine urea hydrochloride they would be of no use because they would probably act as an irritant to the bowel and produce a motion; the passage of the motion would squeeze their contents out again through the needle-puncture hole. On the withdrawal of the proctoscope a suppository is inserted to keep the walls of the rectum apart, and prevent any exudation from causing the opposing surfaces of the mucous membrane to stick together. This would produce pain on defæcation which the suppository will prevent, and, further, the suppository is an additional antiseptic guard. I use "Kuranol" suppositories (Roberts and Co.), which contain bismuth, witch-hazel, and carbolic, and have proved very satisfactory.

After the injection the patients should not do anything active for half an hour. They are sent back to the waiting-room and kept there quietly for the full 30 minutes. Many of them rather protest at this, as they feel perfectly well, but my experience is that if they go straight out they are liable to develop quite intense rectal pain an hour or so later. I can offer no explanation of this, but it is an observed fact, and the rest after the injection prevents it.

There are no sequelæ, except that in about 10 per cent. of the cases the injection is followed by an urgent desire to defæcate. This does not occur, as a rule, until at least ten minutes or so after the injection has been made, so that it need not be an embarrassment to the patient. Bensaude describes it as common, but in my experience it is not. Of complications, likewise, there are none of importance. When injecting the anterior pile-bearing area a certain amount of prostatic pain may be produced, but this does not occur unless the injection is badly made. The patients generally seem more sensitive here and feel the needle more than they do in other arcs of the circle.

Injections should be given only at weekly intervals and from six to eight is the average number required. It is as well to work diametrically across the imaginary clock circle which represents the rectum; that is to say, if the first injection is made at 6 o'clock the next should be made at 12, then at 9, then at 3, and so forth. If a bad injection is made and a pile is entered no harm will occur. The pile will either

remain unaffected or shrinkage will follow in the same fashion as in a varicose vein injected with quinine urethane or salicylate of soda.

It follows as a natural corollary from the general description of the technique that it is no use injecting external piles or piles when they are down. Prolapsed piles can, however, be replaced and the injection made immediately without any trouble. As in all injections of this nature, it is better to wait until the patient is free from any staphylococcal infection of the skin and to have any known septic areas treated before commencing the course.

This seems to be in every way a method of treating piles which deserves respectful consideration. It is painless; it is ambulatory; it is effective, and it can be performed by anyone who will trouble to master the technique. The pathological action—that is, the formation of a fibrosis around the neck of each pile—is a sound one in theory and in practice works well.

Medical Societies.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AT a meeting of this Society held in London on Dec. 21st, with Dr. J. HOWARD-JONES, the President, in the chair, a discussion took place on

MENTAL HYGIENE.

Dr. RALPH CROWLEY said that the Society had not dealt with this subject as a definite part of its work and organisation; therefore some reference must be made to general principles as well as to details. It was a new movement, and those who had spent any considerable time in the United States would have been able to appreciate how great a movement it was. The whole idea of prevention as applied to mental disease, to subnormal mentality and defect, had really burst upon the medical profession. In America the prevention of insanity, delinquency, and mal-adjustments of all kinds could be said to be the talk of the town. This very familiarity, however, constituted a danger—greater in America than it was likely to become here—for people were attempting to deal with the question who were neither expert nor fully qualified. A consequence of this was that false hopes and expectations were raised. The prevention of mental defects and neuroses would probably be much more difficult than the prevention of physical troubles. It was clearly a task which the public health services must take on, though in America it was largely left to private enterprise. So great, however, had been the calls on public health administration in this country during the last 30 years that it seemed almost too much to ask that this new sphere of activity should be added to it. It was not very long ago that the main concern of the public health officer was with the grosser forms of detrimental environment; then, with bewildering rapidity, he had to get into touch with the individual through the infant welfare centres and the school medical services. If the public health officer should now attack the subject of mental hygiene it would make this individual touch even more intimate. Mental hygiene implied an attempt, in a concerted way, to deal with the causes and prevention of insanity, of crime, of delinquency, as well as of those less marked abnormalities which were probably at the base of many of the gross departures from the average. A good deal of valuable knowledge on this matter was now available, but it was not being pressed into service. And he did not think proper use would be made of this knowledge unless it was by the public health services. The work would also bring the medical officer of health into closer touch with other organisations and workers, those in contact with activities in the home, the school, and the court. To get real results in mental hygiene it was necessary to study social aim and method. It was hoped that the result of this new aim would be a uniting of two streams—i.e., the physical and the mental. The actual work would devolve on the expert physician and the expert psychiatrist, and in the future these expert services would be increasingly needed. The public health services provided an unrivalled opportunity for linking up all other activities, and also for planning over a long period of time, for following up, and for making systematic records. There must be channels along which the work of the expert could be made effective. He urged that there must be a concerted mental hygiene campaign by professional and lay workers. Many psychiatrists in America complained of the lack of channels along which their work could flow. The school medical services could make a great contribution in the study of the normal child, giving a definition of "mental health." A well-known authority in America had declared that 250,000 of the boys and girls in high schools would, in time, be in asylums, that a similar number would be in serious conflict with the law, and that a host would have their lives blighted by a variety of causes, many of which could reasonably have been prevented. In this country the proportion of delinquent children was certainly less than in the States, but the lesson was instructive. The key to the situation seemed to lie in the problems of behaviour in children, which so many people regarded as trivial. It was necessary to ask which features of the child's behaviour were transient, which were permanent, which were single traits, and which were accompanied by other manifestations. There was also the further question—what sort of organisation was needed to investigate and find a solution of these problems. He hoped special attention would be devoted to the budding delinquent.

The child-guidance clinics in America had four main functions. They were centres of service for the child, centres of educational propaganda, centres for training (doctors, psychologists, and welfare workers), and centres for research—since every faithful record was a piece of research work. He did not think the main development of this activity would come, in this country, through our hospitals; it must come through more normal channels, those of education, the school medical service, the local health service. Both psychiatrists and welfare workers should be available.

The Adult.

Dr. EDWARD MAPOTHER confined his attention to mental hygiene as it concerned the adult. He laid stress on three of its aspects: the importance of mental disorder, the main defects in the present provisions, and some suggested remedies. To him, mental disorder meant a bodily disease whose main manifestation were abnormalities of behaviour and consciousness. But it must be recognised that the differences which underlay might be merely of the same kind as constituted differences of character and temperament in normal people. They were perhaps more extreme in development, but essentially the same in kind. Mental disease could be divided into organic and functional. There were four main factors in causation: (1) heredity; (2) some abnormality, perhaps incidental to a certain age or epoch of life—such as the menopause; (3) mental stress; (4) physical stress.

In speaking of mental hygiene it was necessary to include a consideration of early treatment as well as prophylaxis in the strict sense. In practice the opportunity for the prophylaxis of mental disorder scarcely arose; certainly it did not in the case of the adult. Some mental disorder arose as a by-product in the struggle against physical conditions which were injurious in themselves. For example, successfully combating venereal disease, or focal sepsis, had as a sequel a reduction in mental disease. In regard to functional mental disorder, prophylaxis in advance of the development of symptoms was, in amount, practically negligible. Positive eugenic measures he

did not regard as practical politics at present; our knowledge of heredity was not yet ripe, and our knowledge of any unitary mental characters which might be transmissible as such was practically nil. No satisfactory methods were available for combating abnormalities arising in adolescence, after childbirth, or in old age. And as for shielding the neurotic or the potential neuropath from stress in advance of his having displayed his attributes, Dr. Mapother was against attempting anything of the sort. Much of the best work of the world had been done by potential neuropaths putting up a great struggle against the risk of a breakdown. In this connexion there was much greater need for a doctrine of courage than for one of caution. But these remarks were not applicable to early treatment which checked the spread or development of mental disorder after its appearance.

The last figures of the Board of Control showed that at present there were in this country 42,000 congenital mental defectives, either in institutions or under some statutory supervision. That, however, was far short of the total number. The cost of these was in large part disguised under such headings as crime and pauperism. The certified insane, in whom mental disorder had developed during life, numbered 140,000. There were 21,000 fresh admissions yearly, and 9000 died, and 10,000 were discharged yearly, leaving an accumulating balance of 2000 a year. No figures were available about the incidence of neuroses, for the reason that nothing was done in connexion with them. But there were some striking neurosis figures furnished by the war statistics. Of the disabilities which resulted in the granting of a pension, 40 per cent. were due to wounds and 60 per cent. to medical disabilities, 12 per cent. of the latter being attributable to neuroses. In peace time, too, a large proportion of the people attending hospital out-patient departments were suffering from neuroses, which, if treated at the beginning, would have been cured.

It was an axiom as regards physical disease that any person in a civilised community was entitled to the remedial measures available for his relief, and if he could not himself pay for it, it was for the community to do so. No similar point of view, however, had been adopted in regard to mental disorder in this country or any other. Here the community —at any rate as a rule—did not concern itself with mental disorder until the patient had reached the stage in which he was incurable. It was only in so far as the person became a burden or a nuisance to others, or showed suicidal tendencies, that his care became the duty of the law or the community. This was a state of affairs which stood a good chance of being remedied in the next ten years. At present, for practical purposes, there was, for the poor, no provision of treatment in the uncertifiable stage of mental disorder. Secondly, there was a complete inability, even for the certifiable patient, to get treatment without submitting to the indignity of a detention order, which necessarily associated him with a number of chronic and protesting patients, though he himself might be quite a willing one. A third, and large, defect was in respect of even those who could pay for themselves, that they could not, if in a certifiable state, have voluntary treatment except in a mental hospital in contact with chronic and protesting patients. The proper way to deal with abuses which might arise through treatment of certifiable people in nursing homes was to insist on the registration and inspection of such homes and the notification of cases admitted to them, power being given to visit with heavy penalties the treatment of cases elsewhere. Whilst there was a good deal of agreement in principle about remedies for defects in present conditions, there was much divergence of opinion on details. The recent Royal Commission had insisted on the necessity of abolishing detailed formalities, and on opening up voluntary treatment of mental trouble in the poor. All were agreed that the two main requirements were research in causation and a very much improved training of medical men, so that they could recognise the beginnings of mental disorder and arrange for the appropriate treatment of their patients. But how far would the real difficulty of obtaining early treatment be solved by the mere reduction of formalities? What deterred the public was the certificate. The objection of early recoverable cases to going into mental hospitals—which he regarded as a reasonable objection—was unlikely to disappear in the lifetime of the average adult now living. It must be recognised that for a considerable period after the onset of mental disorder the treatment should be entirely apart; that the large mental hospitals should increasingly be places for treatment in the later stages of mental disease. The essential requirement was what had been found acceptable in the progressive countries of the world—i.e., the provision of clinics at which early stages of mental disorder were treated on an entirely voluntary basis, these also serving as centres for research and for teaching. This solution might be only practicable in large centres of population; still he felt very strongly that it was an ideal which should be held up as the form of provision really required.

The Child.

Dr. LETITIA FAIRFIELD said that the idea of mental hygiene was a very new one in public health, and it was one of the matters on which America was ahead of this country. In the States people were interested in covering the whole range of mental life with the same thoroughness as the physical was covered in this country. What had been well grasped across the Atlantic was the necessary contact between the school and the public health in relation to the mental hygiene in children. There, for the very young child, had been established "habit clinics," which she had seen at work in a number of cities. The psychiatrist and social worker coöperated in the training of character, and all kinds of help from outside was enlisted. Every factor, such as home life, school, personal associations, and conduct was investigated, and the psychologist determined the standard of intelligence, which was regarded as very important. In this country, when a really intractable failure in a child was met with, there was a tendency to let it slip. There seemed to be no provision for dealing with the very difficult child, and even such conditions as enuresis were allowed to go on, largely because the technique of dealing with them had not been properly worked out. It was, she insisted, very important to lay the foundation of mental hygiene by largely increasing the psychological and character-training side, which had already been started in connexion with child welfare. In large towns at least it might be well to devote one afternoon a week to consultations with a trained psychiatrist. The great bulk of this work would come through the school medical service. There should be less talk of what wonderful things the psychologist could do with cases taken to him from the children's courts or juvenile courts; the great effort should be directed to dealing with them before they got there. The origins of crime often lay in emotional and environmental defects in earlier life which had been allowed to pass untreated. If cases were dealt with at school age they would have been caught before defects had been hardened into habits and before the child felt he had a definite grudge against society because of some punishment received. It was surprising, said Dr. Fairfield, how much an emotional interference with work might keep a child back in school work. The temperamental type of child was very important from the standpoint of the early development of neuroses, and she gave several instances of the perpetuation of the condition into adult life, with consequent lessening of quality in work and continual conflicts with associates. Many people supposed that insanity would be stopped if only an interview with the doctor could be secured early enough; this disturbed people's views and increased their expectations to an unreasonable extent. Hope lay in making provision for nervous and mental disorders on the

same scale and on the same principles as provisions already existed for physical disabilities. It could not be too much emphasised that this was a matter for experts. Apparently simple cases, which seemed to need only common sense, really needed expert handling.

A brief discussion ensued.

Reports and Analytical Records.

BASY BREAD.

(BASY PRODUCTS CO., 4, LANCELOT-PLACE, BROMPTON-ROAD, S.W.3.)

THE claim is made that this bread is a true digestive food and reduces weight without causing flabbiness or wrinkles. When eaten in place of white bread it supplies the necessary roughage to promote functional activity. The crust of the cylindrical loaf is segmented to enable slices to be cut evenly without waste. The weight was 1 lb. 11 oz. and the price 1*s.* 6*d.* It is an agreeably flavoured brown bread.

On analysis the following results were obtained :—

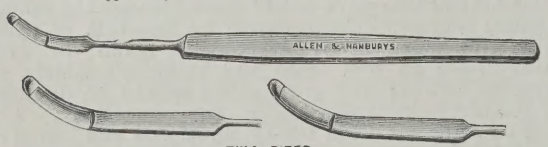
Moisture	38·60 per cent.
Altered starch and dextrin	43·70 ,,
Protein	8·65 ,,
Mineral matter	1·96* ,,
Sugars	4·85 ,,
Crude fibre	1·50 ,,
Fat	0·74 ,,
	100·00
*Containing—Iron (Fe_2O_3)	0·004 ,,
Phosphates (P_2O_5)	0·2 ,,
Matter soluble in cold water	12·28 ,,
Calorie value per lb.	1095

On comparing these figures with those of other breads it will be noted that the fat is distinctly low and the protein rather high, and this tallies with the statement that the bread is nutritive rather than a fat former. The mineral constituents are also on the high side.

New Inventions.

MENISCOTOMY KNIFE.

ACCURATE division of the posterior end of the so-called bucket-handle lesion of a semilunar cartilage close to its attachment to the bone is difficult or impossible with a straight tenotome or other knife. The advisability of dividing the cartilage close to the tibia arises from the occasional finding of a tag at the back of the joint, with its sole attachment to the rest



FULL SIZES

of the cartilage close to the bone. To avoid such a tag being missed, the dividing knife must cut close to the bone in an oblique plane. The curved end of a Macdonald's dissector has been found a useful instrument for determining the precise direction in which the knife should cut. I have, therefore, had made for me a knife with a similar curve, a probe point and a short cutting edge, and this has been found to answer the purpose admirably. Since it is wiser not to use a double-edged knife inside the knee-joint, the knives are made in pairs, to cut to the right and left respectively. Experience has shown that these knives are sometimes useful in knee-joint surgery for purposes other than that for which they were designed.

Messrs. Allen and Hanburys are the makers.

H. A. T. FAIRBANK, M.S. Lond., F.R.C.S.Eng.

Reviews and Notices of Books.

A TEXT-BOOK OF MEDICINE.

By Various Authors. Edited by J. J. CONYBEARE, *M.C.*, M.D. Oxf., F.R.C.P., Assistant Physician to Guy's Hospital. Edinburgh : E. and S. Livingstone. With 16 illustrations and 8 plates. 1929. Pp. 976. 22*s.* 6*d.*

OF recent years there has been a tendency for text-books to be compiled by a series of authors. The personal note may be somewhat lost in the process, and perspective may be a little distorted, but additional completeness and accuracy can be expected, though we are happy to remember that at least one famous text-book was written almost in its entirety by a single author.

Dr. Conybeare's text-book is not entirely the work of his own hand, but he has written the greater part of it, besides acting as general editor. He has had assistance from Dr. W. H. Craib ; from Dr. G. B. Dowling, who contributes the dermatological section ; from Dr. E. H. R. Harries on the infectious diseases ; and from Dr. Maitland-Jones on diseases of children ; Mr. V. E. Lloyd writes on venereal diseases, Prof. H. MacLean on renal disorders, Dr. Geoffrey Marshall on respiratory diseases, Dr. Trevor Owen, of Toronto, on diseases of the liver and pancreas, and Dr. F. M. R. Walshe contributes the neurological section. This collaboration does not lessen the responsibilities of the general editor, since a very high standard may properly be demanded from expert contributors. No large text-book on its first appearance is ever free from slips, but there are scattered through the book a few mistakes that are not trivial. For example, the significance attached to the different tests for ketone bodies in the urine (p. 298) is not that generally accepted. The notes on the van den Bergh reaction, on pages 624 and 625, are neither clear nor correct ; and in the section on oral sepsis (p. 550), though pyorrhœa alveolaris and apical infection are discussed, no mention is made of dental caries.

In the section dealing with the nervous system Dr. Walshe describes the common diseases admirably ; the diagrams are well chosen and suffice to explain the text. Dr. Conybeare has himself dealt with the diseases of the stomach and most of the alimentary canal ; the sections on gastric and duodenal ulceration are very good indeed. The rare type of cancer known as linthus plastica is omitted, though the Plummer-Vinson syndrome receives notice. The unqualified support of surgery in all cases of acute pancreatitis (p. 654) is somewhat surprising. Prof. MacLean devotes most of the space alloted to him to a description of nephritis in its œdematous and uræmic forms. This has been the practice in continental text-books for many years ; Prof. MacLean is careful to explain its shortcomings, but considers that such a classification is of greater practical value to students than one based solely on morbid anatomy. It is open to doubt whether a clinical classification of such simplicity on the surface is likely to prove of advantage to students at a time when it is being gradually abandoned by its supporters and originators on the other side of the Channel. The section on the infectious diseases might be improved by the use of small diagrams to illustrate the age and seasonal incidences of the various fevers. All the accounts in this section are thoroughly up to date and are written in a brisk style. In the section on diseases of the cardiovascular system a plea is made for greater recourse to the electrocardiograph, and the diagrams in this section are drawn from it. The importance of knowing what the heart is doing, rather than what it is saying and murmuring, is constantly kept before the reader. The article on the anginal syndrome is perhaps a little too brief, but all the other parts are well balanced and the essential points made clear. The section on the diseases of the respiratory tract opens with some welcome simplified dogma on the subject of the physical signs

in the chest, continues with descriptions of the chief respiratory diseases, and includes a subsection describing allergic conditions of the respiratory tract. The articles on pneumonia and bronchiectasis have been cleverly condensed. Tuberculosis has been relegated entirely to that part of the book devoted to the infectious diseases; the whole subject occupies only 40 pages of closely packed matter, and can be read in a couple of hours without giving rise to exhaustion, though it could not be properly digested at one reading. We miss a section of psychological medicine and insanity, though diseases of children and dermatology find a place, and the few pages beginning on p. 877 would have been better expanded and amplified into a section separate from neurology.

In his preface Dr. Conybeare points out that he has made no attempt to render the book in any way a substitute for manuals of clinical methods. His aim to produce a complete text-book in as small a compass as possible and at as low a cost has been well attained. If in a future edition space is required for new work, the long description of the history of vaccination on page 45, and the detailed technique described in the following pages could be omitted, for this matter is not strictly essential in a volume in which economy of space has been the plan. It is questionable, too, whether the editor's excellent notes on examination for life assurance are relevant in a volume which deliberately avoids many of the minutiæ found in larger text-books. But the book as it stands is one which can be confidently recommended to students and practitioners. It is clearly printed and it "opens" well. The phraseology throughout is refreshingly clear; new aphorisms and abundant pithy verbal illustrations are supplied, and the index is good.

A TEXT-BOOK OF SURGICAL DIAGNOSIS.

By Various Authors. Edited by A. J. WALTON, B.Sc., M.S., F.R.C.S. Two vols. London: Edward Arnold and Co. 1928. Pp. 1121. 63*s*.

THIS is an important book, being, we believe, the largest work on surgical diagnosis which has yet appeared from the English press. It is a composite effort, the editor having obtained the aid of upwards of 30 contributors, each of whom is an expert in the department of surgery of which he writes. There is one American name amongst them, whose inclusion prevents us from appraising this book as a purely British production. Allen B. Kanavel is known all over the world for his classical researches upon infections of the hand and his teaching has been everywhere accepted; no greater authority could have been chosen.

Volume I. deals with the diagnosis of inflammation, the specific infections, gangrene, shock, hæmorrhage, diseases of the limbs, cardio-vascular and lymphatic systems, head and neck. Contributors are Sir Lenthal Cheatle, Dr. P. N. Panton, Mr. Philip Turner, Mr. Seymour Barling, Mr. E. Rock Carling, Dr. P. Manson-Bahr, Dr. E. C. Hughes, Dr. J. H. Sequeira, Mr. David Lees, Mr. Russell Howard, Mr. H. S. Souttar, Mr. E. R. Flint, Mr. Harry Platt, Mr. H. A. T. Fairbank, Mr. James Driberg, Mr. R. Milne, Mr. Blundell Bankart, Mr. Timbrell Fisher, Mr. Geoffrey Jefferson, Dr. George Riddoch, Dr. W. E. Tanner, Mr. Norman Patterson, and the editor. Volume II. is concerned with the abdomen and thorax, and the contributors, in addition to some already mentioned, include Mr. Tudor Edwards, Mr. Zachary Cope, Mr. W. S. Perrin, Prof. D. P. D. Wilkie, Mr. Gordon Taylor, Mr. Lockhart-Mummery, Prof. S. G. Macdonald, and Mr. Victor Bonney.

The different sections are built up very much as in a systematic text-book of surgery. For instance, in the chapter on Injuries and Diseases of the Pancreas, injuries, calculi, acute pancreatitis, chronic pancreatitis, cysts and tumours of the organ are described with their characteristic histories and symptoms, and the similarity of the clinical pictures to that shown in other diseases is mentioned, as also any special laboratory methods of diagnosis and their value. Ætiology and pathology are discussed where they have a bearing on diagnosis. It is difficult for a writer to know how far to proceed in these directions without transgressing the legitimate scope of a treatise on diagnosis. The authors have without exception shown great judgment and discrimination in the inclusion or rejection of subject matter; throughout the book practically nothing irrelevant or redundant is printed. Mr. Walton in his preface refers to the tendency for operative treatment to outstep surgical diagnosis, and hopes that the volume will be of "real service to the busy practitioner and surgeon." It certainly will—but it falls short in two respects. The first is not a defect in the actual information given, most of which is excellent, but in the plan upon which the book is constructed. How will the busy practitioner who has a patient with a deformed hand, or an enlarged and bent tibia, or a tumour of the neck or orbit, for example, derive assistance from consulting its pages? He will find that he must first give the condition a name and then only will he be able to turn it up and see whether or not he is right in his surmise. The contracted hand of Dupuytren is in one section, two pages further on is a description of the hand in Volkmann's contracture, ten pages later appears an account of the claw-hand of cerebral diplegia; in a completely different section the claw-hand of ulnar paralysis is described, and in still another distant section are the deformed hands due to arthritis deformans or gonorrhœal polyarthritis to be found, these last two not even together but separated by 20 pages. Again, if the doctor suspects a bent tibia to be due to osteitis deformans he can turn up this section and confirm his suspicion, but he will have a difficult search to find any account of a bent tertiary syphilitic tibia, with which Paget's disease may be confused. These two simple examples show how an otherwise admirably written and informative book may fail to supply the needs of the diagnosing practitioner. How much better and more helpful is the regional method of writing a book on diagnosis is seen in sections such as those on the lips, jaws, mouth, and salivary glands, for example, where this system has been adopted.

The second point to which criticism may be directed is the lack of detail in the description of diagnostic measures. In such a large treatise, as large as many complete text-books of surgery for the student, reasonably full accounts may be expected. For instance, suppose the surgeon consults this book on the value of the indigo-carmine test in estimating kidney function. On p. 952 he will find that "with disease of the kidney the appearance of the colour may be delayed (or may not appear at all)," but he will remain in doubt as to how much delay after the "six or seven minutes" when it first appears is really significant of serious functional disease. Again, it would be difficult for anybody to use a sigmoidoscope from the account of "examination with the sigmoidoscope" (p. 630), and no adequate instructions as to how to carry out the manipulations necessary to diagnose a stricture of the urethra are supplied. On the other hand, the technique of thoracoscopy and œsophagoscopy are well described.

Apart from these two points the general standard of the work is uniformly high, no mean achievement where so many authors are concerned, and one which reflects great credit upon the editor. The book is well written, well printed, well illustrated, and accurate. It will no doubt appeal to a wide circle.

LOOKING ROUND, A MISCELLANY.

By Lord RIDDELL. London: George Newnes, Ltd. 1928. Pp. 190. 2*s*.

Lord Riddell, lawyer and journalist, employs a versatile and sympathetic pen to write 17 short essays on persons who have played prominent parts in the drama of public life. Some of these are alive to make their influence felt to-day; some are dead though not asleep; in one way or another each represents an influence. Three of the essays will

make particular appeal to medical men—namely, the biographies of Clemenceau, Huxley, and Sydenham. Of Clemenceau we learn that he comes of a race of doctors long resident in La Vendée, landowners as well, who "being of independent means did not charge for their services," a piece of philanthropy at the expense of the medical profession that was not exercised by Clemenceau himself while he was a Paris practitioner. Of Huxley Lord Riddell says, "Whatever power of accurate thinking or writing I possess I owe largely to him, a debt which hundreds of prominent workers without scientific training must have felt." In "A Medical Saint" we have a brief appreciation of Thomas Sydenham, "one of the five great medical saints" whom the author describes as "a sort of medical Bacon"; the other four saints whom he places in the medical hagiography being, of course, Harvey, Jenner, John Hunter, and Lister. Other personalities dealt with are those of Lord Balfour, Parnell, Sir William Joynson-Hicks, Lord Leverhulme, Lord Bryce, Sir John Simon, President Wilson, Lord Curzon, Augustine Birrell, Mussolini, and a little known mathematical genius, one Scrinivasa Ramanujan, F.R.S. In "A Mysterious Affair" the story is told of Sir Thomas Overbury's murder, which for 300 years has perplexed historians and lawyers. Lord Riddell's summing up of the contradictory evidence, in light of the no less contradictory theories of motive, leads him to suggest that King James was privy to the crime.

HYDATID DISEASE.

Its Pathology, Diagnosis, and Treatment. By HAROLD R. DEW, M.B., B.S., F.R.C.S. Eng., F.A.C.S., Hon. Surgeon to Out-patients, Melbourne Hospital; Jacksonian Prizeman, Royal College of Surgeons of England. Sydney: The Australasian Medical Publishing Company, Ltd. 1928. Pp. 429. 27*s.* 6*d.*

THE prevalence of hydatid disease in Australia has afforded special facilities to workers in that country for the study of its ætiology and treatment. Nevertheless, until comparatively recently, the diagnosis of this serious condition during life has been so difficult and the method of development of the hydatid cyst or the intermediate host so doubtful that an authoritative statement by such a well-known worker as Mr. Dew is welcome. We owe the recent advances in the study of hydatid disease principally to Dr. F. Dévé, of Rouen, and to Mr. Dew himself; others have contributed towards more accurate diagnosis by devising serological tests, amongst whom the name of Hamilton Fairley takes first place.

In this volume Mr. Dew deals with hydatid disease in the most minute and exhaustive manner, giving adequate references to each aspect of the subject. After passing in review the history of *Tænia echinococcus*, he writes on ætiology and prophylaxis with special reference to Australian conditions. There is no doubt that slaughter-yards and abattoirs in that country constitute important sources of infection. An enormous number of sheep are slaughtered annually in Australia for human consumption, and, since the incidence of hydatid disease in these animals is very high, a great number of viscera are rejected as unfit for human food, and some are eaten by dogs who have access to unguarded offal pits. Of all the British Dominions overseas New Zealand and Australia possess by far the greater number of sheep per head of population, the figures standing at 15·3 and 13·3 respectively. Mr. Dew's carefully compiled statistics of the distribution of hydatid disease in Australia will be read with interest; but of greater scientific importance is his account of the development of the cyst in the intermediate host and his interpretation of the various changes which take place within the cyst wall, a subject on which his views, founded on original work, have gained almost universal recognition. In Chapter VIII. are described the special diagnostic methods—by acupuncture, by serological tests, and by the intradermal reaction of Casoni—which help us to recognise the condition during life. A special chapter is devoted to hydatid anaphylaxis and ten others to a consideration of the clinical and pathological manifestations of hydatid cysts in various parts of the body. There are 87 illustrations, mostly original, and all excellent.

Manifestly this is a most thorough and excellent piece of work. Mr. Dew has produced a book which will bring credit to the great hospital to which he is attached.

Hydatid Cysts of the Lung of Children. By M. H. VEGAS, M.D., F.A.C.S., F.R.S.M., Hon. Professor and Member of the Academia de Medicina de Buenos Aires. Buenos Aires: S. A. Imprenta Lamb y Cia, Ltd. 1928. Pp. 300.

THIS brochure, which is dedicated to the American College of Surgeons, deals with a study of hydatid cysts occurring in children. In Argentina, where echinococcus is unfortunately very common, the author has been continuously engaged on this study since 1893. Out of a total of 25,000 children's histories recorded in his archives there are 50 of hydatid of the lung, practically all of which were operated upon by the author himself. Unfortunately, Dr. Vegas has had great difficulty in obtaining access to Australian publications in Argentina with the result that the original work of H. R. Dew and N. Hamilton Fairley has not reached him, and consequently his description of the development of the hydatid cyst differs considerably from the modern view. This matters less in that the chief interest of his book centres upon treatment; the operation of thoracoplasty, as performed by the author, is discussed in detail. A great portion of the work is occupied by details of illustrative cases, which take up over 100 pages, and by a bibliography referring to Argentine publications on hydatid disease.

ASPECTS OF AGE, LIFE, AND DISEASE.

By Sir HUMPHRY ROLLESTON, Bart., K.C.B., M.D., Hon. D.Sc., D.C.L., LL.D. A volume in the Anglo-French Library of Medical and Biological Science. London: Kegan Paul, Trench, Trübner, and Co., Ltd. 1928. Pp. 304. 10*s.* 6*d.*

THIS book, by the Regius Professor of Physic in the University of Cambridge, forms one of a series now being published, in both languages, in the Anglo-French Library of Medical and Biological Science, under the general editorship of Dr. F. G. Crookshank (London) and Prof. René Cruchet (Bordeaux). Sir Humphry Rolleston here reprints 13 papers which have appeared at various times within the past few years in different journals, and has taken the opportunity of making a few additions and amendments. Most of these papers will be familiar to our readers, but it is convenient to have them collected together into one handy, well-printed volume. We are not sure whether it was, or was not, Sir Humphry Rolleston who originated the dictum that when a medical man begins to write on the history of his subject it is a sure sign of senility. The historical papers in this book show how interesting the study of medical history can be made to the average medical man by a master hand; if indeed this skill be a sign of senility we hope that Sir Humphry will long continue to enrich the literature of our profession with like signs. Apart from the historical side, exemplified in the papers on old age, clinical variations in disease from the historical standpoint, and the paper on Samuel Johnson, Sir Humphry is at his best in such subjects as the medical aspects of holidays, poetry and physic, professional careers, and the changes in the clinical aspects of disease. Those of his old pupils who have attended his museum classes and have been his clerks and house-physicians will be glad to have in their possession a volume wherein the philosophy and catholicism of their master is so well exemplified. The book will also appeal to a wide circle outside the profession. The literary output of Sir Humphry has been great; but this little volume of collected addresses will enhance his reputation as a scholarly physician.

THE LANCET.

LONDON: SATURDAY, JANUARY 5, 1929.

THE KING'S ILLNESS.

THE New Year brings but little lessening of the concern with which the KING's illness is watched both in this country and elsewhere. The path to convalescence has proved steep and difficult; almost too steep, indeed, for a man exhausted by so many weeks' infection. Its dangers have been only too apparent, and that many of them have still to be surmounted is clear from the cautious bulletins of HIS MAJESTY'S advisers. The news they contain is amplified in the following statement which has been drawn up for the information of the medical profession:—

"For true understanding of the position it must be emphasised that neither in its inception nor in its subsequent course has this illness conformed to what is called 'pleuro-pneumonia'; rather was it a streptococcal septicæmia which by fortunate happening localised at the base of the right lung, first imperfectly and later as an empyema ('fixation abscess') forming between the base of the lung and the diaphragm. In the second phase of the illness [vide report in THE LANCET of Dec. 22nd, 1928] the clinical picture—dusky appearance, dry cracked tongue, delirium, subsultus, exhaustion—was that of a severe toxæmia and resembling that of a case of severe typhoid fever in the third or fourth week. So now, the picture is that of the aftermath of a severe general infection. The empyema wound is now clean and steadily diminishing in size, the discharge from the pleural cavity is small in amount, and the streptococcus grown from the pus (identical with that originally found in the blood) is diminishing in potency. Eusol has been an effective local application, and though through the courtesy of an American colleague, Dr. Sherman, of Pittsburgh, a supply of Dakin's solution, electrolytically prepared, has been recently received, there has been no opportunity to use it because the necessity of any such local application has passed. On the other hand, the disinclination for food and the dryness of the tongue, the low blood pressure, the weakness and wasting, the notable exhaustion, though slowly improving, will for long be an anxious problem. It will be readily understood that while this exhaustion state is pronounced, the margin of reserve power must be narrow and that small setbacks, inevitable at this stage, have a correspondingly more severe effect. It is important that the public should not interpret such setbacks or reports of 'no change' as relapses. During each week there will be ups and downs, and progress will consist of a slow and increasing predominance of the ups over the downs. One of the inevitable difficulties in so long an illness is to convey to the public a true picture—neither too bright nor too dark. It is for this reason, amongst others, that the courtesy of the medical press is valuable in order to convey, through their readers to the public, fuller information and so avoid the risk of misunderstanding. As regards nourishment, about which so many suggestions have been received, the difficulties will be understood when it is stated that there is disinclination for most foods and dislike for many, and that weakness necessitates that nourishment be given by a nurse with a feeder. Adequacy of nutriment both as regards quantity and variety is now being secured, though not without difficulty. Moreover, the combating of loss of weight, which has been notable, depends not only on food taken, but food digested and assimilated, and here again the exhaustion tells its tale. The blood pressure has fallen too low, and the calcium content of the blood has of late considerably decreased. The administration of calcium, parathyroid extract, and strychnine is apparently beneficial. The same is true of ray-therapy, which is being continued. It need hardly be stated that the question of transfusion has received full consideration. In an illness of this complicated character the indications for transfusion must be clear, and it must be remembered that with the most skilled procedure its employment would in this case entail risk. The striking results following transfusion—e.g., in cases of anæmia due to either hæmorrhage or infection—are apt to lead to its employment in other conditions without adequate consideration of the pros and cons. It is sufficient to repeat that in this grave illness it has been fully considered and put aside at the present stage as definitely undesirable. Moreover, the red blood count is one of the most hopeful features, for whereas in the early days of the illness the red count was as low as 2,900,000, to-day the count reaches 4,300,000. Moreover, the exhaustion is as much a weariness of mind as of body. Though there is an increasing sense of the burden of his illness, the will of the KING to live is there. Because of the exhaustion the course must be long and for the present anxious. None the less improvement and progress are taking place slowly, but surely enough to justify the hope that the KING will be restored to his people."

The note of encouragement with which this statement ends will do much to renew a hope which has at times fallen very low. On the other hand, the obstacles to recovery are frankly set out, and no medical reader will gain the impression that their removal is purely a matter of time. Though there is increasing reason to think that the preservation of the KING's life during these many weeks will not have been in vain, a more definite and settled improvement is unfortunately needed before our anxiety can be replaced by confidence.

HIGH-FREQUENCY CURRENTS IN INTRACRANIAL SURGERY.

WHAT is probably the first attempt on a large scale to use high-frequency electrical currents in intracranial surgery has recently been made by HARVEY CUSHING,[1] and the preliminary results are very promising. In this work CUSHING has had the assistance of that brilliant physicist, W. T. BOVIE, who has provided an apparatus that furnishes a current of 1 million to 3 million alternations a second. By modifying the current in various ways it is possible to produce various different effects upon living tissues, the most important being superficial dehydration, cutting, and coagulation. The apparatus can thus be used to incise the brain and to remove whole tumours or portions of tumours without bleeding, to seal bleeding points, and to bring about massive coagulation of large blood-vessels. The effects depend, as BOVIE points out, "upon the heat developed by the current in passing from the active electrode *into* the tissues, or upon the ohmic heat developed by the current in passing *through* the tissues."

Surgical diathermy or endothermy, as it is called,[2] has hitherto been used almost entirely for the removal of malignant tumours, and one of the chief advantages claimed for it has been the destruction of outlying malignant cells that might escape and seed

[1] Surg., Gynec., and Obstet., 1928, xlvii., 751.
[2] See THE LANCET, 1927, i., 1031.

themselves into the remaining tissues if the operation was performed by scalpel. CUSHING seems to have begun using BOVIE'S machine with this idea, but after a few experiences with malignant tumours he realised that the chief merit of the method for his purpose was that it could cut bloodlessly and without pressure. Accordingly he proceeded to attack large encapsulated vascular meningiomas on the base of the brain—tumours which from their extreme vascularity and inaccessible position had hitherto defied all, or almost all, attempts at successful removal. A large meningioma arising from the olfactory groove and growing upwards into both frontal lobes was encountered at operation; only a small part of its surface could be exposed; but by means of an active ring-shaped electrode it was possible to remove bloodlessly loopfuls of the interior of the tumour—"scalloping," CUSHING calls it—until the shell began to collapse so that it could be taken away entire without any more traction or pressure on the surrounding brain than had been required for the original exposure. This process of piecemeal removal of meningiomas proved tedious and led to operations lasting as long as nine hours; but the results of a series of cases show that a very definite advance has been made. Since the introduction of the BOVIE apparatus two years ago CUSHING has completely removed ten large meningiomas of the olfactory groove with only two deaths, and these among early cases of the series. No longer, he shows, is it necessary to attempt enucleation of these tumours, or of similar growths in other parts of the brain, at the expense of laceration and severe retraction of the surrounding tissue. His next move was to try the effect of electro-surgery on the angiomas—tumours consisting of a congeries of large blood-vessels, whose removal by older surgical methods has usually led to fatal hæmorrhage—and he found that by treating the surface of the tumour with a highly damped desiccating current enough thrombosis was induced to make removal possible at a second operation one or two weeks after the first. In several cases total enucleation of gliomas of the fourth ventricle and vermis was delicately and successfully carried out. Further advances were also made in the treatment of acoustic neuromas.

This work of CUSHING and BOVIE marks a notable advance in intracranial surgery, and it will also arouse a desire for more knowledge of the interactions of electrical currents and living tissues. Thus it may have results that will be of great value not only in the treatment but also in the diagnosis of disease.

THE VIRTUES OF MILK.

ON another page appears the second report of the Scottish Board of Health's inquiry into the dietetic value of milk. It confirms and extends the results published last January,[1] for at all seven centres of investigation the groups of children receiving milk showed a gain in height and weight much greater than that of their contemporaries who got a biscuit ration of the same caloric value. The improvement in the general health was such that the groups of children receiving milk could be picked out merely by inspection. The good effects of adding milk to the diet were, indeed, even more obvious in the period covered by this second report than they were in the previous period, and it was significant that the improvement was mental as well as physical. Dr. C. A. DOUGLAS says that "general alertness was common to all the children fed on milk. . . . It was gathered from teachers and janitors that the children receiving milk were much more alert and very much more boisterous and difficult to control than the others." Another notable result was that with one exception no great difference was observed between the groups getting whole milk and those getting separated (skimmed) milk. This is convincing evidence of the high nutritive value of skimmed milk, but it would be a mistake to conclude from these observations that the part is as good as the whole, and no such conclusion is drawn by the investigators. The conditions of experiment did not permit of an absolute comparison between whole milk and separated milk, for the ration of milk and biscuits was given in supplement to what the children were already having at their own homes. The home diet was an unknown factor in the experiment, and the extent of its deficiencies must necessarily determine the extent of the improvement seen in the milk groups. If, for instance, the home diet included leafy vegetables or butter or a margarine containing vitamin A, the addition of separated milk would probably be nearly as efficacious as the addition of whole milk. Moreover, though height and weight are obvious and measurable criteria of good health they are not the only ones. Another important manifestation of health is the power to resist disease, and here we have good reason to think that even comparatively slight dietetic deficiencies, if sufficiently prolonged, will predispose to infections which find an entry through the mucous membranes of the respiratory and intestinal tracts. The importance of the dietetic factor in determining the resistance to infection may indeed be greater than is at present suspected, and it would considerably add to the value of the Scottish investigation if subsequent reports gave detailed information on the clinical history of the different groups of children.

In commenting on the first report of this investigation we pointed out that the results obtained by addition of milk to the dietary are neither new nor astonishing; nor is such a claim made by those who are conducting it. Two years ago Dr. CORRY MANN published an account of an inquiry on the same lines which gave the same results. In the following year we published a paper[2] in which Dr. W. CRAMER emphasised the exceptionally high dietetic value of milk. He calculated the daily requirement per head as being about two pints—which may, of course, be consumed either as such, or in the form of butter and cheese—and he showed that in this country the actual consumption is far below this figure so far as a great part of the population is concerned. The same view was forcibly expressed by Sir GEORGE NEWMAN in his annual report for 1927. An American authority on dietetics, Prof. E. V. MCCOLLUM, speaks of milk as a "protective food" and arrives at the same figure as Dr. CRAMER for the minimal daily requirement. The fact that in the Scottish investigation the addition of one pint of milk to the diet produced so striking an improvement confirms incidentally the contention that large classes of the population suffer as a result of taking too little.

This reminder of the unique dietetic value of milk comes at an opportune moment. The distress in the mining areas of South Wales and Durham necessarily involves the risk of undernutrition in large numbers of the population, and it is of paramount importance that the funds collected for relief, in so far as they are expended on food, should be spent wisely and economically. The problem is to construct a palatable dietary which satisfies the dietetic requirements at the minimum of cost. Obviously the solution of this problem cannot be difficult, for it is a fundamental

[1] THE LANCET, 1928, i., 202.

[2] Ibid., 1927, ii., 774.

economic problem which the bulk of civilised mankind has always had to face, and it must have been successfully solved by generation after generation. Now it is the dietetic experience of civilised man that a dietary is sound both from the economic and from the physiological point of view if it is built around a basis of cereals and milk. There is nothing in our recent knowledge of dietetics which runs counter to this practical experience. On the contrary, research has justified it. It has also enabled us to understand that in this simple form of dietary the whole cereal cannot be replaced by some refined product obtained from the cereal. In this country cereals are consumed mainly as wheaten bread. The more the caloric requirements of a dietary are covered by bread the more important is it that all the bread eaten should not be white bread, and that at least some of it should contain an adequate admixture of germ or its equivalent. Milk can be consumed either as such or in the form of butter and cheese. Unfortunately, the use of whole milk and of butter is expensive, but the results of the Scottish investigation justify the replacement of whole milk by separated milk provided that a brand of margarine containing vitamin A is used to replace the butter. A dietary, therefore, of porridge, brown bread, separated milk, margarine containing vitamin A, and cheese, would cover almost all nutritive requirements at the minimum of cost. It only requires to be supplemented by the addition of a small amount of fresh vegetable food to make it an adequate diet. If in the distressed areas a basal ration of porridge, bread, one pint of separated milk per head, and an ounce of margarine containing vitamin A were distributed, it would protect the people against most forms of undernutrition; and although in itself such a diet would not be adequate in every respect it is probably better than those on which, from ignorance, a large part of the people of this country now live. On the basis of such a dietary it would be possible to calculate almost to a penny the cost of supplying the distressed areas with food, so that the public and the Government could then appreciate the extent of the task with which they are faced. If the available funds are inadequate to meet the cost it should at any rate be applied to the children and to the nursing and expectant mothers whose health would suffer most from undernutrition. A scheme of this kind recommends itself not only as a measure of properly regulated charity, but also as one of wise economy. For the effects of extensive undernutrition are certain to lay a lasting and heavy burden on the community in the shape of permanent disablement and disease.

THE FUTURE OF GENERAL PRACTICE.

AT almost every hospital dinner someone says amid applause that the general practitioner is the backbone of our profession. Is this only an ancient form of words or does it express a faith alive enough to breed action? The question needs an answer now if ever, for a vague irresolute opinion will do nothing to govern events. General practice is losing its place of first importance in medicine and unless it is regenerated and supported there will be fundamental changes in the structure of the profession as a whole.

The medical needs of the public are always enlarging and varying. At the time when this journal was founded they were mostly fulfilled by a single person, the family doctor; whereas to-day we see a vast machinery of hospitals and public health organisations set up to supplement his efforts in healing and preventing disease. Their work is sometimes said to "encroach" upon his practice, and so indeed it does. But it has all arisen because, for one reason or another, the community could not get from him the care and teaching it wanted. If tuberculosis, infant welfare, venereal diseases, and much of general medicine and surgery have been diverted to clinics and hospitals it is because—from the social point of view—the private practitioner has not been able to cope with them effectively. Sometimes people cannot pay his charges; sometimes they must have institutional care of a kind he cannot given them; sometimes they want more time than he can spare in the daily round; and sometimes they need a skill he does not possess. It has become impossible to unite in one man anything like a complete knowledge of modern diagnosis (let alone treatment), and the public must have, beyond the family doctor, the services of men who have made a study of pathology, radiology, neurology, and psychology—the eye, ear, nose, throat, teeth, and many another specialty Where the poor are concerned society has made arrangements for the care of infectious fevers, insanity, mental deficiency, physical deformity, and a host of other conditions; some of the big industrial firms are taking it upon themselves to look after the health of their employees; and even in the middle and upper classes the scope of general practice is steadily contracting. Many patients like to be treated at hospital rather than at home for their acuter illnesses; parents subscribe to clinics where they can get specialist advice about bringing up their babies; and there is a widespread feeling in favour of the expert as opposed to the merely benevolent. Some say, therefore, that it is the fate of the family doctor to become a sort of shopwalker who will send his patient promptly to the right department and disclaim personal responsibility for knowledge. While agreeing that this may well happen unless steps are taken to stop it, we believe that such a degradation of his functions would be against the public interest. The specialist, like the laboratory, is a good servant but a bad master, and what the average man chiefly needs is a doctor who will shoulder full responsibility for his treatment and take over the burden of his difficulties when he can no longer meet them. He wants someone who will look after *him* rather than his disease, and for this purpose he is best in the hands of a man he knows and who knows him and his surroundings. The hospital may offer skilful nursing and apparatus of investigation; the specialist is indispensable; but neither is the best kind of guide during the indefinite periods of ill-health which are the constant lot of many working men and women. The family doctor can do more than either to influence the daily life of those in his charge, to see that the children are properly nourished and are growing up with no removable handicap to ensure that pregnancy and childbirth shall follow a normal course—in short, to introduce the spirit and practice of preventive medicine into the home.

If it is accepted that general practitioners ought to keep the chief responsibility for the diagnosis, treatment, and prevention of disease—that they should remain the backbone of our profession—we may well ask what equipment and opportunity they are given for holding their own in face of the growing demands of the public. This is not perhaps the time to discuss the whole subject of education, fees, hours of work, holidays, and post-graduate teaching, but it is emphatically the time to consider whether general practice is to lose or gain its life from the legislative changes now approaching. Having suggested that the ideal practitioner should have a good knowledge of diagnosis and treatment, together with an informed

enthusiasm for public health, we are forced to admit that the present system does much to prevent his having either. The young doctor may leave his teaching hospital with a determination to keep up with advances in technique; is it to be certain of his doing so that we make it hard for him to get appointments at his local hospital? He may wish to learn all he can (say) of infant hygiene, antenatal work, tuberculosis, venereal disease and other specialties; is it to ensure that he shall be competent as a practitioner, and shall be imbued with an interest in preventive medicine, that we reserve most of the posts in the public health services for whole-time workers? All this is done in the name of efficiency; and doubtless it is true that a public health department is most easily run by public health officials alone. At the same time experience shows that private practitioners can be successfully enlisted to do this work, and the ultimate advantage of such a plan is beyond all question. Much talk is heard about good feeling between medical officers of health and doctors in their neighbourhood, but the only kind of coöperation that will weld the medical profession, as at present constituted, into a single and efficient instrument, is the coöperation by which young men in private practice are given a large part in working the public services. It ought to be the rule that all those who join a firm as assistants or junior partners should take appointments at the municipal clinics and treatment centres of the locality. At first they would act as clinical assistants and later would hold more responsible posts, their time being adequately paid for on the understanding, of course, that they will look on their public work as taking precedence, during hours of duty, over private interests. Results would eventually justify this policy over and over again, but its adoption needs long foresight. Unluckily, even where well established, it is likely to be put to a severe test during the next few years, for more and more of those who sit on county and borough councils will be in favour of having an easily directed staff of whole-time officers. We shall see an attempt, in the name of symmetry and efficiency, to develop municipal medical services divorced from private practice except in so far as they control and limit it. As a corollary we shall probably see the poor-law hospitals, when they are made over to municipalities, staffed as far as possible by whole-time physicians and surgeons; and if this is done the golden chance of regenerating general practice will be lost. Nothing could be simpler than to set up a hospital service under the public health authorities—a service self-sufficient and self-contained. But to do so would be to condemn the private practitioner to an increasing obsolescence. Without access to hospital for his patients, without facilities for diagnosis or contact with his colleagues, no medical man can properly do the difficult work that is required of him. On the other hand, cottage hospitals up and down the country have shown what can be done by bringing doctors into touch with one another and by offering them better chances of investigating and treating their cases, and we are convinced that to give private practitioners the main part in looking after patients in the municipal (lately poor-law) hospitals would do more than anything else to raise the level of medical practice in this country. To close the doors against them—however convenient and economical this may prove—will be a grave blunder unless it is truly desired that the public service shall ultimately take over all their important duties. The general practitioner can either be brought into the scheme of things or crowded out of it. He can either be doomed or redeemed.

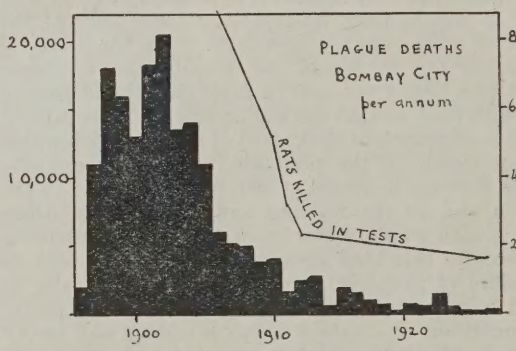
Annotations.

"Ne quid nimis."

MASS IMMUNITY.

MAN'S resistance to infection may be of three kinds: (1) natural immunity (e.g., distemper), inherent in the constitution of the species or subspecies; (2) mass immunity (e.g., measles) acquired by a population having been exposed to the infection in the past and a resistant race having been selected out; (3) individual immunity (e.g., small-pox) from an obvious or suppressed attack or from artificial inoculation. The last two forms almost necessarily overlap in human experience and individual resistance is superadded to a greater or less degree of mass immunity. The resistance of men to any infection no doubt varies just as their every other measurable quality varies. Most individuals have something near the average immunity, some are very susceptible, some very resistant. These qualities are heritable and the progeny of the survivors of any epidemic will be on the whole more resistant than the population in which the epidemic impinged. According to the intensity, duration, and frequency of epidemics the population will become more and more resistant. Such, at any rate, seems likely, though it is hardly possible to prove from human experience alone, that this process actually operates.

Progressive selection by an infection should be easier to demonstrate in small animals: first, because they breed quicker and many generations may come within individual human experience; secondly, because in them sickness generally means death and in consequence the surviving population is not diluted with the offspring of survivors who have acquired individual immunity which is not inherited. Selection under



wild conditions is presumably more intense than when it is interfered with by nurses and doctors, and it seems that a very clear selection of this type has taken place among the rats of Bombay City since plague broke out among them 32 years ago, as may be learned from the very interesting account given by Lieut.-Colonel F. P. Mackie, I.M.S., in the report of the Haffkine Institute for 1927. Plague was introduced into Bombay in 1896 and assumed severe epidemic proportions in the following year. During each of the next seven years from 13,000 to 20,000 people died. After 1905 there was a rapid decline which has gone on progressively and almost regularly till the human deaths in 1926 and 1927 were only 56 and 207. There is no means of measuring with any accuracy the extent and intensity of the corresponding rat epidemics, but it is reasonable to suppose that they have run fairly parallel with the human outbreaks. During this period the resistance of wild Bombay rats to artificial inoculation with plague bacilli has been measured from time to time, with the striking results shown in the table. The conditions of such experiments can scarcely be sufficiently standard to justify minute numerical analysis, but the broad conclusion seems plain—that a given dose of bacilli will now kill only one-fifth of

the number of rats which it would have killed at the beginning of the century. The experiments made in 1910–12 and in 1926–27 have all been controlled by inoculating simultaneously an adequate sample of wild rats from Madras City where plague has never gained a foothold; 95 to 98 per cent. of this unselected

Year	Percentage dying from the test dose of plague bacilli.	Animals tested.	Year	Percentage dying from the test dose of plague bacilli.	Animals tested.
1904	93	111	1912	24	300
1906	95	577	1926	18	848

1911	33	1200			

population died from the test dose. It was also shown by the Advisory Committee in 1910–12 that the young rats bred in captivity from wild Bombay rats were as resistant as their parents.

The present condition has been achieved by 32 epidemics; it is not much different to the position in 1912 after 16. Just how often rats breed in nature is unknown—probably two or three generations a year—and as plague epidemics are annual some generations would escape selection. Roughly speaking, one may judge that immunity is about doubled in 30 to 40 generations. In man this would mean about 1000 years, and as a matter of fact the time has come only lately when any such mass immunity to plague in the people in India might be expected to begin to have an effect. It will be a matter of the most intense epidemiological and biological interest to see whether, after plague has finally died out, the Bombay rats continue to be resistant or whether they will gradually deteriorate to the level of their cousins in Madras.

CRANIAL AND INTRACRANIAL HÆMORRHAGE IN INFANTS.

THE relation of cerebral birth-injury to the nervous diseases of childhood is a problem which remains as controversial as ever. The attempt to correlate the results of autopsies on infants dying of cerebral hæmorrhage with the signs and lesions of children suffering from spastic disorders has so far accomplished little, and the whole question is still in the realm of speculation rather than established fact. Further progress is most likely to come from following up cases which have been thoroughly investigated at birth, and Dr. Donald Munro,[1] of Boston, has lately described an attempt of this kind based on 117 cases over a period of seven years. Whilst his paper includes some objective observations which are of great interest and value, the reader is likely to be impressed by the extreme difficulty of the whole question, and will be wise to adopt an attitude of caution in interpreting the results in terms of causation. The series comprises cases in which a diagnosis of cranial or intracranial damage, including œdema, was made, the basis of the diagnosis being an increase of cerebral pressure (in the absence of surgical shock), in conjunction with such symptoms as cyanosis, refusal to suck, hypertonus, and respiratory abnormality. Of the total 117, no fewer than 54 were first-born infants. Fifty-six died of immediate effects, whilst 58 were discharged as relieved or improved. At post-mortem macroscopical examination hæmorrhage was found in the great majority of the fatal cases, but congestion and œdema alone were found in others, these corresponding to the ones that Munro classified during life as "asphyxial" rather than traumatic. On microscopical examination, however, the asphyxial cases also showed evidence of hæmorrhage, which was usually intra-cortical. The gross traumatic lesions were most often found in the vena magna Galeni or the lateral sinus. Of the 58 babies discharged, all but ten were traced up to December, 1927. Eleven had died, including three with hydrocephalus and one with spastic idiocy; the other seven died of some intercurrent disease. Of the remaining 37, 25 were normal at the end of 1927; 9 were normal when last seen, and 3 suffered from hydrocephalus or convulsions. Munro has presented his results in the form of tables in which the various clinical types are compared, and his deductions depend somewhat closely on this classification. It is to be feared that this fact will increase the difficulty of correlating his painstaking work with that of other investigators. Cases are divided into three groups—traumatic, asphyxial, and hæmorrhagic. He assumes that asphyxia is a cause of hæmorrhage, explicitly attributing one group (16 cases) to it, and therein he may be accused of begging an unsolved question. The assumption is one which most of his fellow workers would probably not accept, for the exhaustive reviews which have appeared in recent years—notably the monographs of H. Ehrenfest and F. R. Ford—indicate that the balance of opinion is opposed to accepting asphyxia as a causal agent, though it may be predisposing or contributory. Moreover, the experimental work on kittens done by Ford, to which we drew attention last year[2] cannot fail to strengthen scepticism about this alleged causal factor, and Munro's figures would have had greater value if so doubtful a major premise could have been eliminated. Of the positive findings in the surviving cases, the outstanding feature is the incidence of hydrocephalus. One of the author's conclusions is that "the most common late result of cerebral damage in the new-born is hydrocephalus associated with either epilepsy or idiocy." The possibility of the hydrocephalus being a late result of a prenatal defect should not, however, be overlooked, and that this is usually so is the considered opinion of W. E. Dandy, Ford, and many other authorities. On the other hand, Munro's view is supported by John Fraser and Norman Dott, who believe that intracranial hæmorrhage plays an important part in the ætiology of hydrocephalus. We hope that in his next communication Munro will deal fully and critically with some of these interesting questions of cause and effect.

FILARIASIS IN OCEANIA.

A MEMOIR, by Dr. P. A. Buxton, on a research expedition into Samoa, Tonga, the Ellice Group, and the New Hebrides in 1924–25 was published in July, 1927. This memoir was principally concerned with the entomology of these lands. He has now published a study[3] of filariasis as it exists in Oceania. In his general scheme of study of filariasis in Samoa and adjacent island groups Dr. Buxton has pursued the methods used by his predecessors engaged upon the same work in that area, but his statistics are more searching and have been calculated on more strictly mathematical lines. Filarial infection in Oceania is rare in childhood. From the age of 11 its incidence rises steadily, and in Samoans reaches 50 per cent. in the age-group from 26–35 years. No constant difference is found in the microfilarial count between those males with, and those without, enlarged epitrochlear glands, and there is no consistent difference in count between communities in which the epitrochlear rate is high, moderate, or low. In other words, *Filaria bancrofti* either produces embryos in the blood and no epitrochlear gland enlargement, or it produces an epitrochlear enlargement, but its microfilariæ fail to reach the blood stream. The glandular signs of filariasis increased with age. Enlargement of the epitrochlear gland was observed in 48·5 per cent. of Samoan males otherwise normal.

[3] Researches in Polynesia and Melanesia. An account of Investigations in Samoa, Tonga, The Ellice Group, and the New Hebrides in 1924–25. Parts V.–VII. (Relating to Human Diseases and Welfare). By Patrick A. Buxton, M.R.C.S., D.T.M. & H., formerly Milner Research Fellow; Director, Department of Entomology, London School of Hygiene and Tropical Medicine. Published by the London School of Hygiene and Tropical Medicine. 1928. Pp. 137 and plates. 9*s*.

Myositis, with multiple abscess formation, which is common amongst the Samoans, but absent in the Ellice, Tokelau, and Gilbert Islands, is not regarded by the author as of filarial origin. Amongst the genital signs of filariasis are marked fibrosis of the testes, epididymiitis, and hydroceles, which are commonly antecedents of elephantiasis in scrotums. Allowing for all the difficulties attendant on the proper study of filariasis, the author concludes that filarial infection is an essential precursor to elephantiasis, but that the exact position of the filaria itself in the pathology of the disease is obscure, at least in Oceania. The common filarial infection of tropical Asia, due to *Filaria bancrofti* with a nocturnal larva, extends eastward and prevails in New Guinea and throughout Melanesia, but the insect vectors in these regions are unknown. In Fiji and Polynesia the filaria with non-periodic larvæ is found, and throughout its area the vector is *Aëdes variegatus*. Certain facts probably account for the absence of the periodicity of microfilaria east of long. 170° E. Even where the microfilaria is nocturnal, the periodicity is not absolute, and a few larvæ may be found in the blood during the day; and it is probable that the non-periodic habit is in some way influenced by the presence of *Aëdes variegatus* in the islands east of long. 170° E. This particular line is of importance in the œcology of the Pacific. West of it the people are Melanesian, malaria prevails, and the microfilaria is non-periodic. Filariasis in Samoa resembles that of Fiji closely, especially in the rarity of lymph scrotum, lymphuria, and chyluria.

Dr. Buxton is to be congratulated on having brought to a successful conclusion a fine piece of work which, in addition to much valuable material, provides matter for further reflection. He deals not only with filariasis, but also with yaws, leprosy, dysentery, and helminthic diseases as seen in Samoa. Part VII. of his monograph is concerned with brown man and white in Samoa, and is an anthropological study of considerable ability, giving an outline of history, customs, and communal life of the people.

CHRONIC APPENDICITIS.

CHRONIC appendicitis is evidently as big a problem in America as it is here, if two recent papers may be taken as a guide. Andresen's [1] conclusions are based on an analysis of 3500 gastro-intestinal cases, and he deplores the results of "misdirected enthusiasm" for unnecessary and ill-directed surgery which has resulted in "thousands of individuals who have not been benefited by appendicectomy." His view is that the structure of the normal appendix (its cilia, its musculature, and the valve of Gerlach at its outlet) is such as to prevent the entry of cæcal contents. Thickening of the wall by inflammation interferes with normal function, cæcal contents enter, and the efforts of the appendix to expel the irritating mass formed by stagnation and desiccation may be the cause of so-called appendicular colic. The appendix does not live for itself alone, and as a rule "chronic appendicitis is only a part of a generalised chronic infection of the whole gastro-intestinal tube and its appendages." In Andresen's series of 586 cases lesions of other organs were demonstrable in 556—that is, 95 per cent. The frequent association of infected tonsils and teeth with chronic disease of the appendix is noted, and also the rarity of concomitant pelvic foci in the female. Diagnosis is difficult, for the symptoms are not characteristic and are readily masked by those arising from the frequent coexisting infection. Similarly, Andresen points out that physical examination is often misleading, and this is undoubtedly true, though we do not think it applies to palpation of an appendix seen on the X ray table. He doubts whether a normal appendix will fill with a barium meal, though it may with an opaque enema, but here again the statement must be qualified, for E. I. Spriggs and O. A. Marxer have shown that if buttermilk is used as a vehicle for the meal, after careful preparation, appendices will fill which otherwise appear impermeable. While reference is made in Andresen's paper to the significance of delay in emptying of the appendix, spasm is not mentioned, though it is a valuable sign, especially if occurring early; the indirect evidence gained by radiographic examination is carefully considered. The general conclusion reached is "that a diagnosis of chronic appendicitis does not necessarily mean . . . an operation." Medical treatment is general (treatment of any coexistent infection or foci) and local. The latter includes dieting with "a normal rough diet" to stimulate the cæcum, meat being taboo; mineral oil is used if required, and general hygienic measures are taken. Such treatment he regards as efficacious and would limit surgery to complications such as kinks and adhesions. Carnett and Boles [2] agree with Andresen about the number of useless operations and in regarding the appendix as only one factor at fault, for they find a constitutional element in many of their cases. The chronic changes seen in the appendix seem to them largely due to a normal evolution and not to disease. Mistakes, in their opinion, arise from confusion of parietal with visceral pain, for they place much of the so-called appendix pain and tenderness in the abdominal wall itself, attributing it to an irritative lesion of the lower intercostal and first lumbar nerves, secondary, as a rule, to a spinal arthritis or malposition. Non-operative treatment is advocated, particularly orthopædic supervision of the vertebral column and adjacent parts. "Patients as a whole would be better off by complete abandonment of appendicectomy for so-called chronic appendicitis." The views reflected in these two papers seem then to be as follows: diagnosis is difficult, treatment must not be limited to the appendix, many useless operations are performed, and there is no one indication on which the surgical result can be foretold. With these views we agree, but would add that cases do occur in which a simple appendicectomy relieves the symptoms. The difficulty lies in recognising such cases.

[1] Medical Aspects of Chronic Appendicitis, by Albert F. R. Andresen, Amer. Jour. Surg., October, 1928, p. 372.

THE NEW FOOD AND DRUGS LEGISLATION.

WHAT used to be known as the Sale of Food and Drugs Acts, 1875 to 1927, were repealed last summer (together with certain amending provisions such as, for instance, those contained in the Milk and Dairies (Consolidation) Act 1915) and superseded by the Food and Drugs (Adulteration) Act, 1928. The new Act takes effect as from the beginning of the year 1929, and will be found a convenient statement of the law in the form of a single orderly document. Two points perhaps should be emphasised in respect of it. In the first place, for drafting reasons, the new Act labels the local authorities which have to administer its provisions as "food and drugs authorities"; the officers who are empowered to take samples are labelled "sampling officers"; these are merely verbal alterations; in other respects there is no change in the law. The second point is that, as usual in a consolidating statute, the repeal of the older enactments is not to have the effect of repealing the regulations made thereunder. This means that the Public Health (Preservatives, &c., in Food) Regulations made by the Minister of Health in 1925 and subsequently amended in 1926 and 1927 are still in force though in part made under the Acts now superseded. These Regulations have also now been printed in the form of a single consolidated document, but there are passages which read awkwardly because of references to the repealed Acts. It would have been preferable to reissue a new code of Regulations without these difficulties even if the awkwardness is not serious. For instance, when Article 6 of the Regulations says that the Sale of Food and Drugs Acts, 1875 to 1907, shall apply to a sample, the reader has to make a

[2] Fallacies concerning Chronic Appendicitis. By John Berton Carnett and Russell S. Boles. Jour. Amer. Med. Assoc., 1928, xci., 1679.

mental substitution and remember that it is now the 1928 Act which is to apply. And, when the Regulations go on to say that Section 14 of the 1875 Act and Section 13 of the 1899 Act shall apply to an analysis, it is now Section 18 (1) of the 1928 statute which is applied.

The Ministry has issued to food and drugs authorities a memorandum on the procedure under the Act explaining the formal differences in the new law and drawing attention to the statutory reports required. It should perhaps be added that the 1928 statute does not apply to Northern Ireland except in so far as it deals with importation. Matters connected with importation and the customs are not within the power of the Belfast Parliament, but with this exception the law of the sale of food and drugs is a matter with which that Parliament is competent to deal.

RADIOPHYLAXIS.

THE strength of growth of lentils germinated on wool at laboratory temperature can be gauged fairly accurately by the growth of the roots. Two investigators [1] in France have taken advantage of this fact in an attempt to discover whether a small dose of radiation has any effect upon the reaction to a large subsequent irradiation. Using 30 Rontgen as a preliminary dose, followed by 450 R. at a later date, and with all experiments controlled, they have come to the conclusion that the small initial dose definitely checks the action of the subsequent larger dose. In all they have made 48 experiments, from which they conclude that there is a definite phenomenon of "radiophylaxis" which seems to account for the apparent non-cumulative action of broken doses in certain experiments that have been detailed by other workers. The bearing of these facts on the application of radiations to the human subject is not necessarily obvious, for we do not know that the response of animal and vegetable cells to radiations is the same. If the parallel could be accepted, it would suggest that the greater efficiency of radiation treatment will be in the direction of massive doses rather than in the fractional dose method now so generally employed. Many of the older workers, however, are convinced of the greater efficacy of the oft-repeated small dose as against the massive dose, so that it seems reasonable not to draw conclusions from botanical experiments until these have been corroborated by similar or parallel experiments on animal tissues. It may be that the well-known latent period of 10 to 20 days in the action of radiations on the human subject has not time to develop in the more rapidly growing cells of the plant.

THE DANGER OF HIGH-TENSION CURRENT.

THE tragic death of a child while undergoing an X ray examination at a hospital recalls attention to the constant need of watchfulness when electric current of high potential is used for the purposes of medical diagnosis or treatment. The evidence given at the inquest is summarised in our medico-legal column. The coroner's jury returned a verdict of accidental death and imputed no culpability to anyone present in the X ray room when the accident occurred. It was accepted by the coroner as scarcely doubtful that the danger zone of the apparatus had been encroached upon by the unfortunate position of an attendant who must unwittingly have placed herself in what was an ideal position to form a complete electric circuit, which when completed was sufficient to electrocute the child. The danger is one which cannot at present be eliminated by mechanical contrivance alone. If the X ray tube is above the couch, as it may be for diagnosis, and must be for treatment, it is practically impossible to eliminate risk entirely, although the risk can be reduced by protecting the cables from accidental contact with anyone who is attending the patient. To surround the cables with cages right down to their connexion with the tube would impede the free movement of the tube which is essential for accurate diagnosis. When the X ray tube is above the couch the cables joining it to the coil or transformer rise from it to the overhead cables, and they cannot be placed out of reach or removed from the possibility of being touched by anyone who is not aware of the danger. A nurse, for instance, might be close to one of these cables, and the patient might raise an arm and bring it near the X ray tube when a spark would be likely to pass through the intervening air gap. The cables must be light and, therefore, cannot be perfectly insulated with any material at present known. The risk is of smaller degree when the tube is underneath the couch, for the cables can then be kept out of reach of careless hands. If the tube is worked from a coil death from electric shock is very unlikely to occur, but in a large proportion of the high-power apparatus now installed the tube is worked from a transformer, when the risk is much greater. In speaking thus of greater or smaller risk it should, of course, be borne in mind that the risk, though present, is very small indeed, and accidents of any kind are very infrequent. Mechanical perfection in the apparatus and the increased training and experience of radiologists and their technical staff has happily reduced the risk to a very small compass, but this fatal accident will have served a useful purpose if it has reminded all who have to do with such electrical installations that they are dealing with lethal weapons in which the human element is still present and that care and watchfulness must never be relaxed.

CANCER MORTALITY IN IRELAND.

WITH the single exception of Switzerland, every country in Europe has recorded increasing rates of mortality from cancer during the last 40 years. In spite of these records there are some who doubt that any actual increase in prevalence has occurred. At a recent meeting of the Section of State Medicine of the Royal Academy of Medicine in Ireland, the President, Prof. Joseph W. Bigger, advanced the proposition that there has been no increase in cancer mortality in Ireland in the last 50 years—supporting his argument by means of tables projected on the screen. The first of these compared certain statistics of 1875 with those of 1925, and established the fact of a decrease in the general death-rate, the infantile mortality-rate and the infectious disease death-rate, associated with a rise in the percentage of total deaths which occurred over the age of 45 years. The second showed a higher proportion of persons aged over 45 years in the population in 1925 than in 1875. Death was ascribed to cancer at the rate of 33·2 per 100,000 living in 1875, and 94·2 in 1925, the increase being chiefly in the age group 45–65 years. Certain other diseases, including ulcer of the stomach and intestine, hepatitis, jaundice and diseases of the liver, ascites, atrophy, and debility, which were common causes of death in persons aged over 45 years in 1875, had greatly decreased or even disappeared in 1925. Prof. Bigger calculated how many deaths from these conditions would have occurred in Ireland in 1875 if the 1925 rates had prevailed, and deduced the excessive deaths from each of these causes in 1875. He argued that a proportion of these excessive deaths (in persons aged over 45 years) were really due to cancer, assessing the proportion at from one-eighth (in enteritis) to one-third (in ascites). These presumed cancer deaths he then added to the actual records of 1875. Turning to "senility" as a certificated cause of death, he pointed out that comparing the later year with the earlier, the deaths so attributed had been greatly reduced, while the number of old persons in the population had increased; 52 per cent. of deaths of persons aged 65 to 75 years were ascribed to senility in 1875, 20 per cent. in 1925. Calculating as before the excess of these deaths in 1875 above what would have been recorded at the 1925 rate, and assuming that certain fractions of this

excess were really due to other causes, Prof. Bigger obtained a further quantum of deaths (recorded as due to senility in 1875) which were probably due to cancer. After applying these corrections to the recorded cancer deaths, the true cancer death-rate for 1875 works out at 95·2, a figure nearly identical with that of 1925. Prof. W. D. O'Kelly, in opening the discussion, asked if cancer was merely increasing because so many people were going into the towns; he assumed that it was a disease of civilisation. Criticising Prof. Bigger's redistribution and the causes of death in 1875, he thought that a large proportion of those attributed to senility would now be regarded as due to heart disease, pneumonia, or bronchitis. Cirrhosis of the liver would absorb a large number of the deaths from ascites ascribed by Prof. Bigger to cancer. Sir John Moore remarked on the part played by surgery in enabling the diagnosis of cancer to be verified before the fatal onset, and on the prolongation of life due to the gradual subsidence of some of the more dangerous epidemic diseases, which permitted the population to live to an age when degeneration due to cancer manifested itself. Dr. W. M. Crofton thought that if the death-rate figures of some easily diagnosable condition such as cancer of the breast or tongue were compared there would be little or no difference between 1875 and 1925. Prof. Bigger, in summing up, said he did not believe that civilisation played any considerable part in the production of cancer; there was, he thought, no great difference in the prevalence of cancer in country and town. A friend of his in East Africa wrote that he had done 12 operations for cancer on natives, thus dispelling the theory that native races are immune. He agreed with Sir John Moore that one reason for the apparent increase in cancer was the prolongation of life owing to the diminution or almost complete disappearance of small-pox, typhus, typhoid, and other infectious diseases. It was difficult, he thought, to place reliance on registration records of deaths in the old days; the improvement in registration of recent times was due to increased medical knowledge among Irish practitioners and dispensary doctors.

HEALTH INSURANCE CHANGES.

THE New Year sees some important changes in the administration of the National Health Insurance scheme, the effect of which will be to simplify its working. Reference to these is made on p. 46. The first change concerns the regulations governing the calculation of arrears in payment of contributions while the insured person is out of work. Certain penalties to be enforced when arrears had lasted so-and-so many weeks are abolished by the new Act, this concession to genuine unemployment being rendered possible by an annual grant out of the Stamp Sales Account. Difficulty in determining whether the unemployment is genuine or not may require the production of certificates by officials of the labour exchanges. Another important change is an extension of what is known as the free year, which is lengthened to 21 months. At the end of this period the approved societies will have sufficient evidence before them to show whether an insured person is entitled to a further period of 12 months' insurance on account of unemployment. The effect of these new provisions will be greatly to diminish the number of notices issued and of complaints which arise from the reduction or suspension of benefits. A voluntary contributor who ceases to pay contributions will remain insured for a period of approximately 21 months as in the case of an employed contributor who ceases to be employed. There will, however, be no further extension, as in the case of an employed contributor, if a voluntary contributor becomes genuinely unemployed; but in this case also sickness will lead to extension of the free year. The provisions relating to deposit contributors are altered very considerably. The fund is divided into two parts, a deposit section and an insurance section. Any deposit contributor may on application be transferred to the insurance section on two conditions: (1) application must be made within a prescribed time and in a prescribed manner, and (2) the applicant must prove that the state of his health is such that he cannot obtain admission to an approved society. If his health improves he must try to obtain admission or failing this he may be reinstated in the deposit section. To provide funds for sickness benefit in the insurance section certain transfers will be made from moneys accruing from interest on the whole funds of the section or amounts standing to the credit of deposit contributors upon death or emigration. There are certain changes relating to the sickness benefit of married women; one such provides that a woman shall not be suspended on marriage where unemployment is due to inability to obtain work; another increases the amount of sickness benefit payable and alters the conditions to some extent.

Alterations in additional benefit chiefly affect the approved society administration and the determination of disposable surpluses. New additional benefits are these:—

(1) The provision of specialist treatment, not being treatment within the scope of medical benefit or any other additional benefit.

(2) Payment to approved charitable institutions in respect of treatment of members.

At the same time certain additional benefits are repealed—namely: (1) medical treatment and attendance for dependents of insured persons; (2) payment of disablement allowance to members not totally incapable of work; (3) payment of pensions or superannuation allowances; (4) payments of contributions to superannuation funds; and (5) remission of arrears.

It must be a continued source of chagrin to all who remain faithful to the health insurance principle that the Economy Act, under which the Treasury grants to insurance funds were reduced, postponed the much-needed laboratory and specialist services. It may be contended that many additional benefits will be available when the sickness claims are reduced, but at the moment we have to face the fact not of surpluses, but for the first time of deficits in many of the funds. The auditor's report for 1927 shows that the total receipts for England were £33,670,000, while the total expenditure on benefits was £30,069,000 and on administration £4,326,000. The English Fund was thus £725,000 to the bad, while the Scottish deficit for the same period was £273,000.

TRANSMISSION OF DISEASE BY TRANSFUSED BLOOD.

WITH the multiplication of blood transfusions in all countries it is inevitable that their dangers should be sometimes emphasised by the occurrence of accidents. The main sources of danger are two: incompatibility of the transfused blood, and diseases that may be transferred with the blood from donor to patient. The first danger is now fairly fully understood, thanks to the researches of Landsteiner and Levine at the Rockefeller Institute and of many others, and it is not often that accidents happen. The transmission of disease also occurs surprisingly seldom when it is realised how difficult it is entirely to guard against it. The two diseases chiefly to be remembered are syphilis and malaria, and it is the duty of everyone entrusted with the task of selecting blood donors rigidly to exclude any individual who could possibly be suspected of harbouring either of them. For the elimination of syphilis the Wassermann reaction must be used as a routine measure, except in an emergency when no tested donor is available. The spread of organisations of voluntary donors in London and the provinces is, of course, gradually eliminating the use of untested donors even when haste is essential. In the earlier days of transfusion several cases were recorded from America in which syphilis was actually transmitted, in one instance from a son to his father; but no case has been published in recent years. Malaria is more difficult to avoid, since there is no test and reliance has

to be placed on the donor's statement that he has never had the disease. The moral of this is pointed by an occurrence described by our Vienna correspondent (p. 44) where a donor, in spite of his statement that he had never had malaria, was proved to have infected four people by transfusions. Other common diseases which have been transmitted in the same way are some of the exanthemata. The transmission of measles in two cases from a mother to her infant was reported from Chicago in 1924,[1] the blood having been taken two days before the appearance of the rash. Small-pox has also been transmitted recently,[2] the blood again having been taken two days before the eruption appeared. The existence of an incubation period must always make the complete elimination of this accident impossible. Much queerer events than these have also been described. On one occasion a patient was temporarily endowed with horse-asthma after having received the blood of an individual subject to this condition.[3] Again, a recent report[4] from Scandinavia records the transfusion of blood from a donor who was seven weeks afterwards found to be suffering from acute myeloid leukæmia, from which he presently died. Fortunately for the patient, if unfortunately for medical science, no symptoms developed in the recipient, so that the question whether leukæmia can be transmitted in this way is still unanswered. It is evident, however, that these accidents are relatively so uncommon that no exaggerated fear need arise in the minds of either the public or the profession. Comfort may also be derived from the statement[5] made in 1925 that the blood of tertiary syphilitics may be safely used for transfusion. It was a somewhat bold experiment, ten non-syphilitic patients being transfused from six syphilitic donors in a late stage of the disease. None of the patients was infected, but the use of such donors is, of course, not to be recommended.

SUPRARENAL TUMOURS IN CHILDREN.

THE exact terminology applied to new growths of the suprarenal glands is often confusing, and in children such tumours are usually so misleading in their clinical manifestations as to render precise diagnoses very difficult. The subject is, however, not really so complicated as is often made out, and a recent report[6] of a case of malignant suprarenal tumour in an infant, with a brief survey of literature, very much simplifies the classification. Tumours of the suprarenal cortex either give rise to no symptoms at all, like the simple adenomas, or produce curious disturbances of sexual development. Tumours of the medulla of the suprarenal are in reality new growths of the sympathetic nervous system, and the term "neuroblastoma" is used for them, or more simply "medullary sarcoma of the suprarenal." These latter tumours are especially liable to cause difficulty, for they metastasise so early that, the secondary deposits seem to dominate the picture, while the primary growth may only be discovered at autopsy. Tumours of this variety fall into two groups. The "Pepper" type occurs in babies between six weeks and four months old, usually growing in the right suprarenal, and giving rise to an enormous enlargement of the liver which is diffusely infiltrated with secondary deposits. The "Hutchison" type is, as a rule, found in children between one and five years of age. The primary growth, usually in the left suprarenal, is bigger than it is in the Pepper type, while secondary deposits occur in the bones, especially those of the skull. It is in such cases that difficulty may arise because secondary deposits in the orbit, producing proptosis, may occur before the primary growth is discovered, and the diagnosis from chloroma can often only be made from a blood count. In the paper from which this review is taken van Veen describes a case of the Pepper type in an infant aged only 18 days. The main clinical feature was the huge size of the abdomen due to an enormous liver. Blood count showed a slight decrease in the red cells with an increase in the leucocytes. The van den Bergh reaction in the blood was negative and so also was the Wassermann reaction. The child died at the age of 6 weeks, and at the autopsy the liver was seen to be very large, pale, speckled, smooth, hard, and infiltrated throughout with metastases, while the primary growth was in the right suprarenal with a somewhat compressed right kidney. Dr. van Veen discusses the histological appearance of the tumour and its relationship to the sympathetic nervous tissue. His observations may be correlated with those of Dr. D. M. Greig,[1] who in a paper which has just appeared gives an account of the histological appearances of the Hutchison type, describing fully a case in which there were secondary deposits in the region of the right side of the face and skull. He is interested especially in the nature of cephalic metastases in these cases, and points out that the secondary deposit is in the soft tissues at first and infiltrates the bone later. After a period of bone absorption there is great activity of the bone cells with local excess of calcium salts leading to formation of new bone. This bone cell activity is the direct result of the excess of vascularity which the highly vascular tumour has ensured. In Greig's case the primary growth was in the right suprarenal, which is a slightly less common site than the left suprarenal for the primary focus. He quotes the work of Frew to show that the cephalic distribution roughly follows the side of the primary growth, owing, it is believed, to the anatomical arrangement of the lymphatic drainage of the suprarenal glands.

HOSPITAL AFTER-CARE AT SHEFFIELD.

ANONYMOUS generosity has made it possible to inaugurate a valuable scheme for after-care and convalescence at the Sheffield Royal Infirmary. There, as elsewhere, it has been felt for a long time by the infirmary board that the work of an institution of 500 beds was incomplete if it ceased automatically when the patients left the wards. It is desirable in the ex-patient's interest that his progress should be carefully watched, his diet supervised, arrangements made for further examination and treatment on the first sign of retrogression; and equally desirable in the interests of posterity that complete records of progress should be available as a guide and control to the treatment of others. We are to-day at a period in hospital development when we must appraise our results more intelligently in order more accurately to register what we are accomplishing. The patient must be followed actually to his home or place of work in order to estimate how his physical condition is standing the strain of normal life. Valuable information will be obtained from an after-care scheme with a well-organised follow-up and a collation of the data so obtained. In the case of the Sheffield Infirmary scheme the primary functions are several, and may be epitomised thus: to gain knowledge of the patient's condition after discharge from hospital; to coöperate with any and every agency with a view to rapid restoration to health; to help the patient to understand the treatment recommended, prescribed, and often supplied by the hospital; to furnish where necessary surgical appliances, artificial limbs, splints, trusses, and the like; to supply drugs like insulin and special diet for diabetics who cannot take the food of the ordinary household. The scheme is drawn up specially with a view to convalescence; in accordance with the wishes of the founders expressed in a trust deed the fullest use will be made of convalescent homes, particularly of homes offering special treatment. The word convalescence is to be construed in its broadest sense, and under this heading will be provided home nursing

[1] Edin. Med. Jour., January, 1929, p. 25.

where needed. The Sheffield Royal Infirmary has for a number of years past employed an almoner in the capacity of inquiry officer and assessor of means. This work will form part of the new after-care department, the registration of patients being one link in the chain which will keep the patient in touch with the hospital from the time of entering it until health is restored. The appointment of women specially trained for this work is under consideration, and it is hoped to open the new department shortly. Sheffield is to be congratulated on the generosity of the two benefactors who have made the scheme possible, and the Royal Infirmary on the foresight shown in the arrangements for making it a success.

RESEARCH INTO ASTHMA.

ON Jan. 15th the Lord Mayor of London will inaugurate a national appeal for funds, to enable the Asthma Research Council to develop a well-conceived scheme of investigation into the cause and treatment of asthma and allied disorders. Since we gave publicity last spring to the aims which prompted the establishment of the Council, its Medical Advisory Committee has been expanded to include men who work in widely separate parts of the country and whose angles of approach to the problem of asthma are even more distinct. Their names are set out in a letter (see page 50), wherein the immediate plans of the Council are summarised. Membership of the Medical Advisory Committee involves not only general counsel but active coöperation, since it is proposed to establish throughout the country research centres, financed by the Council, under the supervision of individual members of this Committee. The Royal Infirmaries of Liverpool, Edinburgh, and Manchester, the Stobhill Hospital, Glasgow, the General Hospital, Birmingham, and the Royal Victoria Hospital, Belfast, have already consented to supply facilities for research on these lines, and other provincial hospitals are considering the question. Laboratory investigations will be carried out at Edinburgh, Bristol, and at King's College Hospital, and St. Mary's Hospital. In London, clinics are being formed at Guy's Hospital under the direction of Dr. H. W. Barber, Dr. R. D. Gillespie, and Dr. Arthur F. Hurst, and at the Hospital for Sick Children in Great Ormond-street, where Dr. E. A. Cockayne will take charge. Both these clinics are financed by the Halley Stewart Trust endowment, which has made a grant of £2500 spread over four years for this purpose. At Guy's the clinic is especially designed to supplement and complete an investigation into the biochemical causation and treatment of asthma which is being undertaken by Dr. G. H. Oriel under the auspices of the Medical Research Council. It is proposed to carry out a controlled survey of the effects of different sorts of treatment on selected cases. The physicotherapy in use at various continental spas has excited the interest of the Council, and under a grant from the British Humane Association Dr. Una Ledingham has been appointed Research Fellow to study technique. She has visited Reichenhall, Mont Dore, Ems, Hamburg, Berlin, and Paris, and is now testing the methods favoured at these centres in this country, on suitable patients, by means of apparatus installed by the British Humane Association. Saline and pine oil inhalations, automatic breathing apparatus, expiratory exercises, nasal gas applications (CO_2), ultra-violet light, and diathermy are all being tried.

The businesslike way in which the Asthma Research Council is setting up a well-designed network of small centres throughout the British Isles deserves high praise. The well-established variations in manifestations and response to treatment of asthma may eventually be correlated with variations in geology, flora, or even clan. Since the climatic factor looms so large if not in the pathology certainly in the treatment of this strange disorder, there is every reason for decentralisation of activities. It is a wholly unexplained fact that while one asthmatic is well only in a warm dry climate, high above sea-level, his brother—sometimes literally his brother—is free from attacks only in low marshy areas. Light may be thrown on these discrepancies in members of families subject to asthma and the curious disorders of the skin and other systems sometimes associated with it, by the questionaire on family history which is being circulated by the Council. Forms have been prepared for the collection of statistics concerning the influence of heredity on the whole asthma syndrome. These forms are available in duplicate in order that control charts of non-asthmatic families may be prepared, and medical men are urged to coöperate in the research by distributing them among their patients. The help of the afflicted may properly be enlisted in order that the £50,000 required for the establishment of investigation centres and the development of research schemes will speedily be raised. The headquarters of the Asthma Research Council is at 42, Ranelagh-road, London, S.W. 1, and it is to this address that inquiries should be directed and donations sent.

Mr. John Humphrey Plummer, of Southport, has left about £250,000 to the University of Cambridge in order to endow two chairs for the promotion of modern scientific research.

THE annual congress of the Ophthalmological Society of the United Kingdom will be held in London from Thursday to Saturday, April 11th–13th. On the Thursday, at 2.30 P.M., Mr. E. Maddox, Group Captain Cecil Clements, and Mr. Charles Goulden will open a discussion on Heterophoria, and on the Friday, at 8 P.M., Sir Arnold Lawson, Dr. R. A. Young, and Mr. S. A. Browning will speak on the Diagnosis and Treatment of Ocular Tuberculosis.

THE City of Cardiff is about to lose the services of the medical superintendent of its mental hospital, Dr. Edwin Goodall, who has decided to retire from active work there in April. The hospital was Dr. Goodall's own creation, for he came to Cardiff from the Carmarthen Mental Hospital in 1906 to supervise the preparation, furnishing, equipment, and staffing of the new City Asylum, which was opened in 1908. Under his direction the institution has acquired all the equipment considered necessary for the up-to-date mental hospital. There is a full staff of visiting specialists, a radiological and ultra-violet installation, an operating theatre for general and special surgical work, and a hydrotherapeutic department. Nearest to Dr. Goodall's heart is the biochemical laboratory, built in 1910, at a time when biochemistry was associated with psychiatry in the minds of only a very few. It is equipped with sterilising and instrument room, bacteriological apparatus, and a department for physiological research, and over 50 original papers have been published by its staff, recent work including research into phosphorus, calcium, and cholesterol in the blood, and basal metabolism in mental disorders. Nor has Dr. Goodall neglected pioneer work in the treatment of early mental disorder, for he has been physician in charge of the psychiatric out-patient clinic at the Cardiff Royal Infirmary since its inception, and he has exerted himself in the field of legislative reform. During the war his institution became a hospital for wounded soldiers. The City Mental Hospital is happy in retaining Dr. Goodall's services as a consultant.

BRITISH CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.—The seventh congress will be held in Dublin from April 24th to 26th, under the presidency of Dr. Gibbon FitzGibbon. The chief subject for discussion will be Disproportion, but there will be papers on many other subjects besides, and an exhibition of pathological specimens will be arranged. It is hoped to have a representative gathering from all parts of Great Britain and Ireland, and those wishing to take part should communicate as soon as possible with either of the joint honorary secretaries, Dr. Bethel Solomons and Mr. Gerald Tierney.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XVII.—THE INTERPRETATION OF BREAST HISTOLOGY.

WITH ILLUSTRATIVE PLATE

Facing p. 11; Legends to Figures on Plate on p. 11.

A CLINICIAN seeks the services of a pathologist in two circumstances: first, to report upon the condition of the breast and tissues after operation with the objects of confirming the diagnosis and of ascertaining the distribution of disease with a view to prognosis, or to the necessity or not of further treatment; and secondly, for the purposes of making a diagnosis when the clinical signs are not sufficiently definite to ordain the particular line of treatment. In this article features of outstanding importance are demonstrated which should enable a clinician to follow the descriptions of the pathologist. The clinician must not infer—under these circumstances—that the parts of a breast that were not removed are in the same state as those that were removed. It may happen that the early carcinoma of a cystic breast may exist in the parts left behind.

In order to obtain the best results the pathologist and clinician should work together in the closest coöperation. If possible they should examine the patient together before operation, and after it the pathologist should remove the portions of tissue he requires for his examination and report. If this desirable course is impracticable the clinician should give the pathologist as complete a clinical report of the breast and patient as he possibly can. Invaluable pathological reports are based upon whole microscopical sections of the entire parts removed. I have carried out the method of cutting whole sections for 25 years, and my knowledge is based chiefly on this method, but as yet it has not been generally adopted. Where the method of cutting whole sections is impracticable it is well to get as near to it as possible by means of smaller ones. When only that segment of the breast has been removed which contains the localised nodularity, or lump of doubtful nature, the wound should be immediately and thoroughly washed out with a 1-1000 watery solution of perchloride of mercury, to kill any epithelial cells that may have been squeezed out during the process of excision, and to prevent transplantation of carcinoma cells in the event of the lesion being malignant. This lotion should be used even if the parts were removed by diathermy.

In order to guide the clinician a pathological report upon a breast lesion should include the precise state of the epithelium and connective tissues. The report should be arranged on the following pattern by dividing it into two categories: (1) the state of the epithelium, and (2) the state of the connective tissue.

THE STATE OF THE EPITHELIUM.

The state of the epithelium will be discovered to be among the three classes: (*a*) genetic, (*b*) desquamative epithelial hyperplasia, and (*c*) dysgenetic epithelial hyperplasia. Hyperplasia of this type is a tumour immediately the process begins.

(*a*) *Genetic.*

This class includes all normal epithelial hyperplasia. The morphological appearances of all breasts at birth (male and female), at puberty, and in pregnancy and lactation bear very close resemblances to each other. In all these conditions new ducts and acini are being formed, and these epithelial new formations are always accompanied by hyperplasia of the pericanalicular and periacinous connective tissue. Lymphocytes are often seen among the fibres of the latter tissue. Whenever the breast appears normally active, the epithelium and the pericanalicular and periacinous connective tissue take part in that activity.

The development of breasts is incomplete at birth in both males and females; the morphological appearances are chaotic and variable at this age. Sometimes the epithelial columns that dip down from the skin and penetrate and branch amongst the subjacent connective tissues look very like carcinoma. At others places the hyperplasia of the pericanalicular and periacinous connective tissue appears like a highly extravagant condition of what is commonly called "chronic mastitis."

At puberty and lactation the same tissues are active, but in a much more orderly form than they are at birth. It will always be impossible to understand the condition now described as "chronic mastitis" until it is realised how closely the changes at puberty and lactation (Figs. 1 and 2) are imitated and reproduced in "chronic mastitis" (Fig. 3). A breast in this condition has a marked physiological relation to active normal breasts, and this relation will be made clear when this subject is being discussed (see below). A breast in chronic mastitis is merely one in a state of activity when it should be at rest. The development and formation of the common fibro-adenomata in breasts at puberty will also be more fully understood when its fabric is compared to those tissues which are undergoing physiological hyperplasia in the same breast at the same time.

FIG. 3.

Lobule of a breast suffering from mazoplasia. A, duct full of irregular-shaped, badly staining shed epithelial cells. The acini are also full of shed epithelium. At B there are some newly formed acini. C, pericanalicular and periacinous connective tissue which has undergone hyperplasia in which many lymphocytes can be seen. Strands of the supporting connective tissue of the breasts can be seen separating adjacent lobules from each other.

(*b*) *Desquamative Epithelial Hyperplasia.*

Epithelial hyperplasia is desquamative when the process ends in the shedding from the surface of the epithelium of cells which are incapable of separate existence and of multiplying, and which finally die. The process is normal in development, in puberty, in pregnancy, and during lactation. It is pathological in two types: (*a*) in *mazoplasia* ("chronic mastitis"), and (*b*) in *cystophorous hyperplasia*. I consider the separation of mazoplasia from cystophorous hyperplasia to be of great importance. They are different

processes; they can exist as independent conditions; neither of them has any connexion with "chronic inflammation." Mazoplasia is an unimportant state in its relation to all other tumours except—like puberty—to fibro-adenoma. It is a very common state, sometimes producing pain during life, and it can be frequently seen in breasts post mortem, where no complaint of pains had been made during life. It cannot be regarded as being in an important relation to carcinoma and papillomata. On the other hand, cystophorous hyperplasia is a cyst-forming condition related to tumour developments, and is a definitely pathological state.

Mazoplasia (chronic mastitis).—This condition has no possible ætiological connexion with an inflammatory process, and I therefore propose to give it the new name of mazoplasia.

In mazoplasia the acini and terminal ducts throughout the breast are filled with desquamated, small, irregular-shaped, badly staining epithelial cells. As in the normal active states of the breast there is also a hyperplasia of the pericanalicular and periacinous connective tissue, among the fibres of which lymphocytes may be common or absent. New acini may form in the lobules. The state resembles the breast at puberty also in another respect. The fibro-adenoma that is a typical tumour in a breast at puberty is very liable to occur in the state of mazoplasia, and new acini may form in the fibro-adenomata of both conditions. The fibro-adenomata of puberty and mazoplasia consist of an enormous and more or less local hyperplasia of the pericanalicular and periacinous connective tissue.

The anterior and posterior surfaces of the actual breast in mazoplasia are smooth on palpation. The nodularity of the cutaneous surface on which the diagnosis of "chronic mastitis" is so often made (and is commonly supposed to be so typical of the condition), is due to the fact that the terminal branches of the ligamenta suspensoria enclose fat lobules which, on palpation, give rise to the sensation of multi-nodularity of the surface of the gland. The multi-nodularity completely disappears if the branches of these ligaments are cut across by undercutting the skin, and it is not caused by a nodularity of the gland itself. A large amount of fat between the breast and the skin masks clinical signs in the breast and hides localised true nodularity and lumps of the gland where, in thin breasts, they would be palpable. The picture seen of mazoplasia in Fig. 3 need give no grounds for anxiety except for the possible formations of fibro-adenomata. It may last for years and is likely to cease after the menopause. Mazoplasia does not end in cyst formation, and cannot be regarded as a proemial state of—or as a prelude to—carcinoma. The generalisation of the pain in these breasts is the only important symptom of mazoplasia, and hence, for the purposes of diagnosis and prognosis, is not a symptom that suggests anything more dangerous. Focal pain at one part of one breast is a much more serious symptom, whether it appears alone or in a localised nodularity in either a thin or fat breast.

Transillumination of the breast, recently proposed as an aid to diagnosis in breast lesions by Max Cutler, of New York, is a valuable help. In normal breasts and in mazoplasia the Cameron light renders the gland translucent. Any localised shadow shown by transillumination indicate the presence of a tumour. Cysts, however, are translucent and cannot be differentiated from the rest of the breast by transillumination.

Cystophorous Hyperplasia.—In the cyst-forming type of desquamative epithelial hyperplasia the morphological appearances are distinct from those of any other lesion in the breast. The appearances are so peculiar that they have been mistaken by others for the sweat glands of the skin. I am sure they are true breast structures, and can always be connected up with normal breast ducts by making serial sections.

The cystic dilatations are caused by the desquamative epithelial hyperplasia which occurs in the acini and terminal ducts. At A in Fig. 4 the process can be seen occurring in a transverse section of a terminal duct in which large shed colostrum-like cells are arising in all stages of formation from the epithelial wall. The acini into which this duct leads are also in a state of desquamative epithelial hyperplasia (see Fig. 4, B and B_1). In some parts the cells are feathery and in others more stunted. In the acini the hyperplasia is often a little more than one of mere desquamation and in parts small papillomata have formed as well. At other parts, before the epithelial cells are finally shed they have piled themselves on the top of each other to form columns of epithelial cells only.

The morphological appearances are so typical that there should never be any doubt about the diagnosis. One terminal duct and its acini may be affected only (see Figs. 4, 5, and 6). The whole of only one duct and its branches and acini may be affected and occupy a whole segment of a breast or many terminal ducts, and acini may be affected and scattered with no particular arrangement about the whole of the gland. The state may be unilateral or bilateral. The confluency of affected acini form the common large cysts of the breast.

Dysgenetic epithelial hyperplasia can be detected occurring in cystophorous hyperplasia (see Figs. 5 and 6), a fact which at once converts the latter into one of more potential importance than mazoplasia by showing it is one that is a prelude to more dangerous types of epithelial hyperplasia. In small cysts the epithelial hyperplasia is more active than in the large ones.

There must be such stagnation of contents in the cysts as would allow a contained irritant to act undisturbed and for a long time; this may be the explanation of a harmless type of epithelial hyperplasia developing into one that is dangerous. Whether this be the explanation or not, there can be no doubt about the fact that tumours—papillomata and carcinoma—arise in the cysts as additional complications. I regard cystic breasts as proemial to these complications, and are very likely to contain one or more examples of tumour formation. For instance, I have discovered carcinoma in seven cystic breasts in which its presence was not even suspected, and in others a variety of tumour formation.

(c) *Dysgenetic Epithelial Hyperplasia.*

Epithelial hyperplasia is dysgenetic when it results in the pathological formation of living cells which are capable of multiplying. Dysgenetic epithelial hyperplasia forms a tumour from the moment of its inception and occurs in four separate conditions.

1. The epithelium may more or less retain its normal appearances, although it covers papillomata (see Figs. 6 and 7). Papillomatous formations in the ducts may even develop into a focus of breast glandular structure containing ducts and acini.

There can be no doubt that papillomata may exist for years without any further complication than an intermittent spontaneous discharge of blood from the nipples; in fact they may exist without any clinical signs at all, and be accidentally discovered in association with carcinoma elsewhere in the breast. In spite of the apparently insignificant course this purely papillomatous state may run, I consider it to be a dangerous state for the following reasons:—

There is no clinical sign upon which it can be decided whether there is a single papilloma or whether there are multiple papillomata. To discover a papilloma in one part of a breast does not exclude the probability of others in the unexamined parts of the same breast. When they are multiple they are just as dangerous as the condition of multiple papillomatous adenomata of the large colon which invariably ends in carcinoma. (Lockhart-Mummery and Cuthbert Dukes.) There is a distinct connexion between carcinoma and papillomatous formations. During the development of "tar cancer" in mice it is very common indeed for the area painted by tar to develop benign papillomata before carcinoma becomes established.

For all these reasons my outlook on the discovery of a papilloma is to regard it as a sign of potential—or of the existence of real—danger that demands the removal of the breast. In this connexion it must also be realised that an intermittent spontaneous

discharge of blood from the nipple may be induced by a benign papilloma or by a multiplicity of benign papillomata, by a duct carcinoma, and more rarely by a carcinoma developing from a dysgenetic epithelial hyperplasia in terminal ducts and acini (see Fig. 8).

2. The individual epithelial cells which result from the process may be arranged in a sessile manner unattached to any stalk of connective tissue (see Fig. 5). They may show signs of malignancy by exhibiting nuclear hyperchromatosis, variation in the size and shape of the cells, and mitosis, and I am convinced they are malignant, and yet the process may be still confined within normal boundaries of ducts and acini (Fig. 7).

3. In Fig. 8 the definite state of carcinoma is reached; some of the epithelial cells described in the preceding paragraph (2) have escaped into the surrounding tissues.

Some highly malignant tumours—of the thyroid gland, for example—may appear morphologically to be normal and give rise to normal secretions. Tumours of this class would still be dysgenetic in type because, however normal they look, they are pathological in growth and behaviour, and form metastases.

4. A pure adenoma may occasionally arise in the breast; it usually does so at the age of puberty and grows with great rapidity. Sometimes the patient is considerably older. It is a benign tumour.

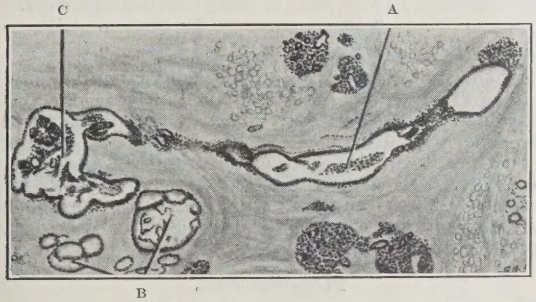
Pathological Changes in Connective Tissues.

A report on the condition of the epithelium would not be complete unless it contained a description of its relation to the connective tissues of the gland.

A. *The State of the Intra-Elastica Connective Tissue.*

This tissue exists immediately beneath the surface epithelium of ducts and acini, and consists of a single layer of unstriated muscle fibre on which the epithelial

Fig. 6.



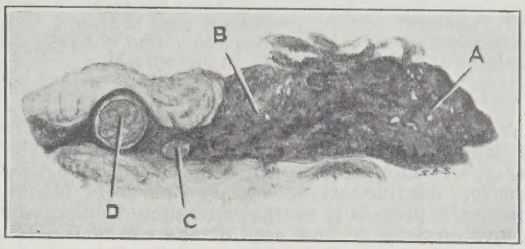
The figure has been drawn from a section of a terminal duct A and C leading into its acini B. The portion of the duct A and the acini B are in an active state of the cystophorous hyperplasia type 2. The portion of the terminal duct C is being distended by a dysgenetic epithelial hyperplasia which has undergone a papillomatous formation which is strictly limited within the normal boundaries of the duct. There was carcinoma elsewhere in this breast, for which it was removed.

cells lie, and loose connective tissue composed of scattered branching cells among a delicate fibrillous matrix. The intra-elastica tissue becomes most obvious when it undergoes hyperplasia, which it may do in terminal ducts and acini. It is usually quite localised in situation and never occupies large areas of the gland. Its condition and situation in a duct can be defined only when the elastica is especially stained. It is important pathologically because it gives origin to localised tumours which may grow and bulge into the ducts, forming small papillomatous growths; or it may be the site of origin of large fibro-adenomata (intracanalicular). When it exists in the presence of carcinoma it is the first tissue to be invaded by epithelial cells, before they reach the elastica. Hyperplasia of this connective tissue is often present in more or less degree when there are other pathological activities in the same breast, for which search should be made, and in this respect it resembles hyperplasia elastica.

B. *The State of the Elastica.*

Normally the elastica consists of a narrow, well-defined layer of elastic fibres outside the intra-elastica connective tissue of ducts. It is directly continuous with the subepithelial elastica of the nipple, areola,

Fig. 9.



A whole section (natural size) of a segment of a breast. The segment was removed because the fibro-adenoma D was discovered clinically. Microscopical examination revealed two important and common events. There is another fibro-adenoma C, and at B the breast has undergone a diffuse hyperplasia of the pericanalicular and periacinous connective tissue. The fibro-adenomata D and C were also composed of a much more localised hyperplasia of the same connective tissue. The age of the girl was 15½ years. The rest of the breast (A) shows marked regular hyperplasia of the pericanalicular and periacinous tissue amongst which lymphocytes are present. There is also a regular and extensive genetic new formation of acini.

and skin. It may occasionally surround some acini by a single narrow defined line, and it may here and there surround a lobule. It becomes pathological when it undergoes hyperplasia, which it may do to an enormous degree and be represented by more than 100 per cent. of its normal amount (see Fig. 8). In a state of hyperplasia it commonly surrounds acini as well as ducts, so that it must be assumed that the connective tissue forming part of the wall of the acini possesses the potentiality of forming elastica.

Hyperplasia elastica may affect the ducts and acini of the whole gland or it may be quite localised to a few ducts only. Hyperplasia elastica may occasionally exist alone, but usually it accompanies other forms of pathological hyperplastic activity, which should always be searched for when hyperplasia elastica is present. For instance, the elastica can be demonstrated to have undergone enormous hyperplasia round some terminal ducts and acini which contain the malignant epithelial hyperplasias from which the invading epithelial cells have escaped to establish the presence of carcinoma (see Fig. 8). Often the elastica may be absent—it is so at birth—and even later in life none can be detected in some glands even when the elastica of their blood-vessels stains normally.

Too often isolated deposits of carcinoma are described as being multiple foci of multicentric origin. If a deposit shows only the carcinoma cells in tissues where epithelial cells ought not to be, then that focus must be definitely described as a secondary deposit only. If, on the other hand, a terminal duct and its acini (Fig. 8) can be demonstrated full of epithelial cells identical in appearance with those invading outside structures, then it can definitely be described as a primary focus of carcinoma. In order to be quite sure that the tube is a duct and not a distended lymphatic vessel the elastica of the duct must be stained.

C. *The State of the Pericanalicular and Periacinous Connective Tissue.*

When discussing genetic epithelial hyperplasia I definitely stated that this particular connective tissue undergoes hyperplasia in states of normal activity and nearly disappears when the gland is at rest. It is an intimate component part of the true breast structures and it should be so regarded. The pericanalicular and periacinous connective tissue

usually becomes pathological by undergoing an excessive localised or diffused hyperplasia when it is normally active in the rest of the breast.

For example, the fibro-adenomata of puberty is composed of an excess of the pericanalicular and periacinous connective tissue which is being normally active elsewhere (Fig. 9). In fact a fibro-adenoma or fibro-adenomata (they are often multiple, see Fig. 9) of puberty may be regarded as being a more or less localised excess of the physiological activity that is present in the rest of the gland. This physiological likeness is increased when a fibro-adenoma of puberty contains newly formed acini which are also appearing in the rest of the breast at the same time. Again, appearances which are normal at birth, puberty, and in pregnancy and lactation become pathological when they are present at a time when the breast should be at rest—for example, in mazoplasia.

CONCLUSIONS.

A pathological report upon the state of epithelial hyperplasia should allude specifically to these epithelial states, and should state whether the hyperplasia be genetic, desquamative, or dysgenetic. If it be *genetic* the process is normal and should not give rise to any anxiety on the part of the clinician. If the epithelial hyperplasia be desquamative it is important to state whether it belongs to type (a) *mazoplasia*, or type (b), *cystophorous hyperplasia*. If it belongs to type (a), *mazoplasia*, there need be no anxiety about the future, except as regards the possible formation of fibro-adenomata. It is improbable that the condition would be complicated by the formations of papillomata or carcinoma. On the other hand, if it belongs to type (b), the *cyst-forming* type, the clinician will at once have the following grounds for anxiety: 1. There is almost the certainty of constant trouble arising from the appearances of fresh cysts. 2. A cyst may contain an epithelial hyperplasia which is no longer desquamative, but has become dysgenetic in type; therefore, however small the lesion may be, it is an epithelial tumour (see Figs. 5, 6, 7). The tumour may be papillomatous in type, sessile in type, or sessile and malignant in type, yet all these types may be contained within normal boundaries. No notion can be made as to how long they may thus continue. The papillomatous states are known to last a long time. For all I know the sessile benign-looking state and the sessile malignant-looking state may sometimes disappear entirely. On the other hand, if either of them progress, carcinoma is the inevitable result. Finally, if the epithelial hyperplasia is *dysgenetic* in type, the pathologist should state whether it is papillomatous and confined within normal boundaries, or whether it has transgressed them to become a duct carcinoma. Is it sessile and benign-looking and confined within normal boundaries? Or is it malignant-looking, but still confined within normal boundaries? Or is it a carcinoma? When pain is generalised over both breasts and no lump or local nodularity can be discovered, the gland belongs to the mazoplasia group and calls for no further treatment than support, attention to the psychic condition of the patient, correction of pelvic ailments, and the application of X rays or radium; the gland may be excised if the pain becomes unbearable. As to dysgenetic epithelial hyperplasia of the breast, its future treatment—so far as present knowledge is concerned—seems to depend upon how far the efficiency of radium can be trusted. It is possible that all forms of this type may be annihilated by the efficient application of radium. Until that time arises it is by far the safest course to remove by radical operation all breasts that are cystic and all breasts that contain dysgenetic epithelial hyperplasia. In the case from which Fig. 5 was drawn sufficient would have been done if all the ramifications and acini of the whole of the involved duct had been excised—a perfectly impossible operation. The same treatment would not have been indicated in the case from which Fig. 7 was drawn; unsuspected carcinoma was discovered upon microscopic examination of whole sections of the gland.

MILK CONSUMPTION AND THE GROWTH OF SCHOOL-CHILDREN.

SECOND PRELIMINARY REPORT ON TESTS TO THE SCOTTISH BOARD OF HEALTH.

BY GERALD LEIGHTON, O.B.E., M.D., F.R.S. EDIN., HON. D.SC. SYRACUSE,
MEDICAL OFFICER (FOODS) TO THE BOARD;
AND
MABEL L. CLARK, L.L.A.,
ROWETT RESEARCH INSTITUTE.

THE preliminary report by Dr. J. B. Orr on the result of the 1926–27 investigation into the feeding of a large number of school-children has already been published in THE LANCET (1928, i., 202). The conclusions which might be drawn from that work appeared to the committee in charge of the test to be so interesting and important that it was decided to continue the investigation over a further period of equal length.* That has been done and the present report deals with this period of the repeated test—namely, November, 1927, to June, 1928.

The seven centres at which the investigation was carried out were Peterhead, Aberdeen, Dundee, Edinburgh, Glasgow, Greenock, and Belfast. The number of children involved was 1425. At each place four groups of children were selected and each group treated differently. One group received whole milk, another separated milk, a third a biscuit ration of the caloric value of the separated milk, while a fourth acted as controls, receiving nothing.

The children of	13–14	years received	1	pint of milk daily.
,,	9–10	,,	1	,,
,,	6–7	,,	¾	,,

All the milk was given at the schools under supervision. The whole milk was pasteurised, except at Peterhead and Aberdeen, where it was "Certified." The separated milk was machine-skimmed. Samples of all the milk given were taken monthly and sent to the Rowett Research Institute, where they were analysed. These analyses show that the average fat percentage of the whole milk was 3·85 and that of the separated milk 0·33.

Measurements.

The measurements were all done by one of us (M. L. C.) and were done four times everywhere except at Belfast, where they were done three times. As in the 1927 test the children were all weighed and measured in indoor garments and without shoes. This year the heights were recorded to the nearest eighth of an inch and the weights to the nearest quarter of a pound. To obtain a fairly accurate *average* increase in weight a careful record was made at each weighing of every article of clothing worn by the child, and from these records the average weight of clothing for boy or girl was calculated. The difference between the initial (winter) and final (summer) weight of clothing was then added to the final gross weight. In Belfast in three schools the children were weighed in one garment only, and the difference between winter and summer weights was therefore the exact increase made by the child.

To obviate fluctuations, as far as possible, the weights and heights were taken at the same hour of the day

* Owing to the death of Dr. Lewis Cruickshank and to the absence of Dr. J. B. Orr abroad, it was decided to place the organisation of the second investigation in the hands of Dr. Gerald Leighton. This also enabled the Board's wide knowledge of the nutrition of school-children and the implications of such in connexion with public health to be more readily utilised.

on each occasion, this being in the case of children receiving milk before the milk was drunk. As far as possible the schools were visited in the same rotation in order that the period between initial and final weights and heights might be identical. On each visit an accurate record was obtained for each child of all absences and illnesses. Thus the exact amount of supplementary feeding was known. Any child who had missed 25 per cent. of feeds, or showed other abnormality, was excluded when calculating the results. The number so excluded was 268.

Special Conditions of the Investigation.

In considering the results of this investigation the following points should be borne in mind. The number of children involved was very large, no less than 1157 being available for the measurements from which the tables are compiled. These children were divided among seven centres of population in which the test was conducted simultaneously. Their ages ranged from 5 years to 13 years, including the beginning, the middle, and the end of their ordinary school life. All the children in the six Scottish centres were living in the ordinary conditions of Scottish working-class homes, and received the ordinary diet of such homes. The milk and biscuit given to them at the schools were therefore in the nature of a *supplementary ration to their home food.* The results therefore must be regarded as the effect of the addition of definite quantities of milk to the average home diet of children of school age living in ordinary working-class conditions in industrial centres. It would appear to be justifiable to infer that the same results, whatever they may be, would apply to the whole school population living their ordinary life. Those conditions, from the standpoint of a nutritional investigation, are, of course, very complicated, but this test was so devised as to bring out any *significant* differences which might arise within the limits laid down.

The following three tables show the total results of the investigation.

TABLE I.—*1928 Increases. Milk* versus *Non-Milk Groups and Percentages.*

—	No.	Height increase.	Weight increase.
13-year groups—			
Milk	137	1·4699 in.	5·6387 lb.
Non-milk ..	133	1·1908 in.	4·2368 lb.
		= +0·2791 in. —i.e., 23·44 %.	= +1·4019 lb. —i.e., 33·09 %
9-year groups—			
Milk	188	1·3943 in.	3·4202 lb.
Non-milk ..	212	1·1068 in.	2·0495 lb.
		= +0·2875 in. —i.e., 25·98 %.	= +1·3707 lb. —i.e., 66·88 %.
6-year groups—			
Milk	242	1·5021 in.	2·5331 lb.
Non-milk ..	245	1·2398 in.	1·8531 lb.
		= +0·2623 in. —i.e., 21·16 %.	= +0·6800 lb. —i.e., 36·70 %.
All age-groups—			
Milk	567	1·4585 in.	3·5776 lb.
Non-milk ..	590	1·1810 in.	2·4610 lb.
		= +0·2775 in. —i.e., 23·50 %.	= +1·1166 lb. —i.e., 45·37 %.
1927 Increases (Scotland—all ages)—			
Milk	551	1·470 in.	3·617 lb.
Non-milk ..	731	1·212 in.	2·974 lb.
		= +0·258 in. —i.e., 21·29 %.	= +0·643 lb. —i.e., 21·62 %.

From Table I. it is seen that taking all the ages combined of the 1157 children and dividing them into milk-fed groups and non-milk-fed groups, there is an average increase in height of 23·5 per cent. and in weight of 45·37 per cent. in favour of the milk-fed groups over the non-milk-fed groups. It is also seen that these increases are greater in this second and repeated test than they were in the first (1927) test.

Table II. shows the increase in height and weight in all the age-groups with the number of children in each group. In every case the milk-fed children are

TABLE II.—*1928 Increases in Age-Groups.*

Whole milk	121	1·5589	2·7107
Separated milk ..	121 (487)	1·4452	2·3554
Biscuits	115	1·2424	2·1609
Controls	130	1·2375	1·5808
Total number.. ..	1157	—	—

ahead of the "biscuit" and "control" groups. The greatest increase in height is in the 6 year old milk-fed group. The greatest increase in weight is in the 13 year old separated milk group. The difference between the "biscuit" group and the "controls" is but slight except that the 13 year old "controls" did better in height but not so well in weight. In the 6 year old group the "biscuit" group is better in weight than the "controls."

In Table III. there is set forth the mean increase in pounds and inches (i.e., for weight and height) in each group at each age, together with the probable error involved and the significance or otherwise of the differences.

Other Observations.

In addition to the foregoing statistical observations two other lines were adopted which do not permit of being stated in figures.

Dr. C. A. Douglas examined all the children clinically when they were measured. Her report states that—

"In practically every case it was noted that the children receiving milk showed, even where there was obviously poor maternal care, that sleekness peculiar to a well-nourished animal. Their hair had a glossy and bright appearance. Their nails were smooth, resilient, and looked as if polished. General alertness was common to all the children fed on milk. No difference could be detected with regard to these points between the children receiving milk irrespective of the kind of milk. It was gathered from teachers and janitors that the children receiving milk were much more alert and very much more boisterous and difficult to control than the others. This latter fact was only too evident when they were waiting in small groups to be weighed."

Dr. G. W. Simpson made a different observation. He asked the headmasters to parade the children in their respective groups, he himself being unaware which group was milk-fed or otherwise. From this general survey he placed the groups in order of apparent standard of nutrition. Of five examinations thus made he found that first places of nutritional standard were accorded to three whole-milk and two separated milk groups. Second places were accorded to two whole-milk and three separated milk groups. Third places were accorded to all five biscuit groups, and fourth places to all five control groups.

"The difference in nutrition between groups receiving milk and not receiving milk was plainly evident. No great difference was noticed between the whole milk and separated milk groups."

TABLE III.—1928 NUTRITION TEST.

Those familiar with the manner in which statistics of this kind are worked out will be aware that, in order that the difference between two groups and figures may be regarded as "significant," that difference must be at least three times as great as the "probable error." The results in this table are calculated on that basis.

A sixth examination did not correspond with the other five, but in this case the best nourished children had been selected as "controls," while those apparently needing the milk most were put into the milk groups. The desired conditions for observation were thus not fulfilled.

would occur two of the previous feeding groups were reversed. A group which in the first investigation received separated milk now received biscuit. Another group which in the first investigation were "controls" now received whole milk. The general result in both cases was that they changed places, the former milk group now receiving biscuit fell to the biscuit standard, while the former "control" group now receiving milk rose to the milk standard. Table IV. shows the detailed results of this reversed test. Table IVA. shows similar details for the other areas (groups continued not reversed).

Conclusions.

As the result of this repeated investigation (1927–28) it may be said at once that the tentative conclusions drawn by Dr. J. B. Orr from the first investigation were more than justified. The great value of an additional milk ration to that already taken at home is clearly demonstrated for all ages of school-children.

In the repeated test the average increase in height in the milk-fed groups in all ages combined is actually *1·21 per cent. more than in the first test.* The average increase in weight in the milk-fed groups in all ages combined is no less than *3·75 per cent. more than in the first test.* Not only have the same milk-fed children benefited again, but they have done so to a greater extent than before. Their initial improvement has *continued over the second year.*

Once more the value of separated milk for children of school age is shown. In most groups the difference in height and weight between the whole milk and separated milk groups is not "significant," but in the 6 year old group whole milk is "significantly" better than separated for both weight and height. In every case the whole milk and separated milk groups are better than the "biscuit" or the "controls." In this repeated test the difference between the "biscuit" and the "controls" is usually "insignificant"; the effect of the extra biscuit appears almost negligible. The improvement of the milk-fed groups in general health and appearance is clearly brought out in the reports of Dr. C. A. Douglas and Dr. G. W. Simpson. Many of the teachers have recorded similar opinions.

When these results are considered, along with those published by Dr. Corry Mann in this country and those of observers in other countries, the only conclusion possible is that they have a wide public health significance, especially with the nutrition of school-children.

"In 1903, when the Royal Commission on Physical Training (Scotland) issued their report, two things became clear: first, that medical examination and superintendence were essential conditions of any system of physical education; second, that in the end *the fundamental problem is one of nutrition.* . . . When every preventable ailment is prevented, and every serious disease treated to its finish, the new battalions of children coming forward have to be superintended from the nutritional standpoint."—Sir Leslie Mackenzie.

The two reports of this investigation fully substantiate these views.

Committee of Investigation.

The investigation was conducted under the direction of a Committee appointed by the Scottish Board of Health with Sir Leslie Mackenzie as chairman. The members consisted of the school medical officers for the cities and towns where the work was carried out.

We desire to thank Dr. J. F. Tocher, Aberdeen, and Mr. J. S. Thomson, Rowett Research Institute, for advice and help on the statistical side of this investigation. The results of the investigation have also been submitted from time to time to Prof. A. P. Cathcart, chairman, Nutrition Committee of the Medical Research Council.

The cost of the investigation was defrayed by a grant made by the Empire Marketing Board to the Rowett Research Institute, Aberdeen.

MEDICINE AND THE LAW.

Failure to Provide Medical Treatment for Child.—Rebutting Medical Evidence Called by Defendant.

THE parent who has been prosecuted before the Wolverhampton magistrates for neglecting his child in a manner likely to cause unnecessary suffering, in that he refused to sanction an operation for the removal of the child's tonsils,[1] made his final appearance before the bench on Dec. 16th. The Distributist League, of which Mr. G. K. Chesterton is president, had undertaken his further defence. Counsel, instructed by Birmingham solicitors acting for the League, said he desired to make it clear that, if an operation was considered to be the only possible remedy, nobody suggested that the operation should not be performed. The child had now been examined by four London consultants, two of whom were tendered as witnesses, while statutory declarations had been obtained from the other two. Dr. Fergie Wood stated that the little girl's tonsils were very much enlarged, but that he could not find any evidence of her health having suffered. He did not recommend an operation, but suggested a treatment. Dr. Bertrand Allinson said he found the tonsils enlarged and a slight deafness in the left ear. He, too, recommended treatment—a strict diet and breathing exercises; he said he would resort to surgical operation only as the very last remedy. Counsel for the defendant submitted that the parent, so long as he followed the advice of responsible doctors, could not be said to be failing to provide adequate medical aid for his child. The father, in the witness-box, expressed his willingness to allow the child to be examined monthly by a school doctor, and it was agreed that copies of the doctors' reports should be given him.

It may be recalled that the Wolverhampton bench, at the original hearing of this charge, was satisfied that the prosecution had made out its case, but that sentence was postponed for a month with the idea of seeing what action the defendant would take in the interval. The Deputy Town Clerk, appearing for the Wolverhampton Education Committee, explained that the Committee had not insisted on an operation, and that, if there were any other treatment which would effect a cure, such treatment would be regarded as adequate. The magistrates fined the father 40*s.* and dismissed the charge against the mother. They took the view that the father had failed to procure adequate medical aid for the child, although he had now agreed to adopt treatment to prevent the suffering caused to the child in the past. As was suggested in these notes recently, the evidence (above described) which was tendered to show that an operation was unnecessary might appropriately have been offered by way of defence to the charge, rather than as an afterthought in mitigation of sentence. The benevolent intervention of the Distributist League, whose mysterious title presumably conceals a policy of advocating individual liberty against State interference, has provided the material for defendants in future proceedings under Section 12 of the Children Act in enlarged tonsils and adenoids cases. It has to be borne in mind that, while the prosecution is presumably obliged to specify the medical or surgical treatment which the accused person is alleged to have neglected to provide, the magistrates have no power to order an operation; all they can do is to put pressure upon a defendant by suspending sentence with the hint that no punishment will be imposed if the medical advice is followed.

X Ray Apparatus Accident.

An unfortunate accident at the Royal Infirmary at Hull was investigated by the Hull coroner on Dec. 18th. A girl, 8 years of age, had fallen on the ice and broken her arm, and was taken to the Infirmary for X ray examination. During the third examination a

[1] THE LANCET, Nov. 24th, 1928, p. 1081.

nurse moved to another part of the room, and by so doing completed an electric circuit, with the effect that the child was killed, the child's mother (who was holding the child's hand) received a severe shock and the nurse also was injured. Dr. C. R. Moore, who was in charge of the X ray apparatus, said he gave the usual warning to those in the room not to touch the wires. Dr. J. E. Bannen, hon. radiologist to the Infirmary, explained at the inquest that, by going to the dangerous side of the table while the high-tension circuit was in operation, the nurse unwittingly placed herself in an ideal position—even if she did not actually touch the wires, but merely went near them—to form a complete electric circuit sufficient even at a low voltage to kill the child. There was no efficient method, he added, for insulating the leads. The jury returned a verdict of "accidental death." The coroner stated that there was no question of any culpability on the nurse's part; she had given her evidence with commendable candour. The admission to the X ray room of inexperienced persons was, he remarked, a question to be considered by the infirmary authorities.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Transmission of Malaria by a Transfusion of Blood.

AN unusual occurrence was disclosed recently during a discussion at a medical society in this city. The facts were as follows. A middle-aged woman, brought to a gynæcological clinic in Vienna, had to be operated on at once on account of an extra-uterine pregnancy. Both before and during the operation she lost a great deal of blood, so it was decided to perform a transfusion. From the list of donors who are at the disposal of the clinic, one was selected who was known to have acted in the same capacity three times before, and his blood was used in the ordinary way. The woman's condition picked up rapidly, but some time afterwards she developed high fever, and was transferred to a medical clinic, where the diagnosis of tertian malaria was made and confirmed. As she had never before suffered from malaria, the donor was at once suspected and was submitted to an examination, which showed the presence of plasmodia in his blood. He contended that he had never suffered from malaria—indeed, that he had never had any fever at all, and had not been outside Vienna. It was possible to trace the three other patients to whom he had acted as donor, and these also proved to have been infected. They had suffered from time to time from attacks of fever, but the right diagnosis was not made until they were summoned to the clinic for investigation. This incident shows the need for an exhaustive examination of donors, not taking too much account of a negative previous history.

The Health of Vienna.

The Federal Board of Health of Austria has published a report on certain factors which influence public health and the fluctuations of the population. During 1927 the population of Vienna was estimated at 1,866,147, and the deaths at 26,379. The number of marriages was 16,256, and the decrease of population (excess of deaths over births) was 5042—that is to say, twice what it was a year ago. No case of cholera, small-pox, typhus, or epidemic meningitis was reported, but 880 persons died from suicide, 43 were murdered, and there were 658 fatal accidents. The number of medical practitioners in the city was 4519, or 468 more than in 1924 (an increase of 11·5 per cent.), and 110 more than in 1926 (an increase of 2·8 per cent.). For the whole of Austria the increase was 872—i.e., 12·2 per cent. over the figure for 1924, or 4 per cent. over that for 1926. The mortality in Vienna was 14 per 1000 in the population as a whole, but for the medical profession the rate was only 9·8. A marked increase in the mortality figures was caused by the rapid spread of diphtheria and measles last year, especially amongst school-children. Whereas in 1926 only 99 persons succumbed to diphtheria, last year the figure rose to 198, and against 9 deaths from measles in 1926 there were 133 in 1927. Therefore the Board of Health is urged to reconsider its previous order which abolished the necessity of notifying measles to the district officer of health, and is recommended to introduce one of the numerous methods of prophylaxis against this disease.

Diseases of Over-feeding.

Dr. Kollert discussed recently in the Medical College for Post-graduates the problem of conditions produced by excess of food. He said that in eclamptic uræmia fat is excreted in the urine, and œdema is very often noticeable. During the later part of the war, when there was a scarcity of fat in the daily fare, fat in the urine, as well as uræmia eclamptica, was almost unknown here, although there were numerous cases of nephritis. With reappearance of fat in the daily food the old conditions returned. Cirrhosis of the liver was also very rare during that period, whilst diabetic troubles and Graves's disease became much less common. Observations amongst primitive races seem to prove that an almost exclusive meat diet predisposes to early arterio-sclerosis. Over-feeding with vitamin B, he believes, distinctly encourages enlargement of the spleen and lymph glands—the "lymphatic habitus" of the older writers, who already suspected faulty feeding as a causal factor in this condition. Excess of vitamin D, he said, seems to promote calcification of the large blood-vessels. But all these relations are not yet thoroughly investigated, and only one fact stands out clearly—namely, that diseases run a different course according to the kind of feeding which the patient had before his illness.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

The National Insurance Bill.

AFTER many years of contemplation a Bill providing for national insurance has been introduced to the Commonwealth Parliament. In 1923 a Royal Commission investigated the problem but the present proposals are only approximately based on the recommendations of that Commission. Financial provision is made against sickness, disablement, widowhood, orphanhood, and superannuation. Medical benefit is not included. Workers who have a total income exceeding £416 will not come under the terms of the Bill. Sickness allowance of £1 7*s.* 6*d.* per week is payable to male adults, £1 per week to female adults, and 15*s.* per week to minors unless married. After 26 weeks the maximal allowance is reduced to £1 per week. In the event of death the widow would receive £1 per week for at least three years, and 5*s.* for each child under the age of 16 years. A superannuation allowance of £1 per week is payable at the age of 65 for males and 60 for females. The contributions that will entitle the insured person to these benefits will be 1*s.* per week, plus a further 1*s.* contributed by the employer. Women will each contribute 6*d.* It is stated that the proposed scheme "will follow the general lines of the British National Insurance," but this does not satisfy the commercial section of the community, who fear that it will be an added burden to industry. Employers have a vivid recollection of a child endowment scheme in New South Wales which was designed to benefit the married men by increasing their wages in proportion to the size of their family, but actually forced the married men out of employment and increased the cost of living.

Throughout Australia there is evidence that voluntary contributions for hospital maintenance

are falling away, so that increased claims are being made on public funds. The grants per bed to hospitals, from the funds of the respective State Governments at the present time, are: Victoria £45, Western Australia £83, New South Wales £99, Queensland £102, Tasmania £105, and South Australia £149. Victoria endeavours to increase the voluntary contributions to hospitals by means of a central fund known as the "Lord Mayor's Fund." During the financial year 1927–28 the total amount collected by this organisation amounted to £61,642. Queensland conducts a State lottery in the interests of the medical charities. For the financial year 1927–28 the disbursements from this source amounted to £335,610.

The function of the Victorian Bush Nursing Association is to provide trained and resourceful nurses who will undertake general nursing, obstetric, first-aid, and child welfare work. It was started in 1911 and there are now 59 bush nursing centres in Victoria. Considerable interest has been aroused by the records of the obstetric work of the Association.[1] For the past 12 months 792 cases were delivered without a single death. Antenatal supervision was given in 715 of these cases.

A Noise Abatement League has been founded in Melbourne. One reason for this is that the Melbourne Hospital is situated almost in the centre of the city, and the traffic noises in the surrounding streets are considerable. An intending benefactor of some importance has stated that he is not prepared to give a large donation to the hospital unless steps are taken to remove the tram lines from the contiguous streets. The Tramway Board has given the request serious consideration, but there are tremendous difficulties in the way. The situation has revived local controversy about the desirability of placing a general hospital in the centre of a city.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

A Source of Tropical Drugs.

INDIA has a source of great potential wealth in its home-grown drugs, an industry which only requires the attention of the people to develop on economic lines. The chemist and the pharmacologist can help in different ways. Many of the drugs used in Europe and America, for which some sort of standard has been laid down, grow in various parts of India. Chemical or biological assay of all these can be gradually made and their value relative to those growing in other parts of the world ascertained. It will be necessary not only to assay the plants growing wild in different parts of India, but also to find out their seasonal variation and the soils in which they grow best. Russian artemisia growing wild has been found to have a santonin content of less than 1 per cent., which is increased by cultivation to nearly 3·6 per cent. Russia accordingly at present is the best source of santonin, but artemisia grows wild in some parts of the Himalayas, in Baluchistan, and in the Hindu-Kush mountains. India could supply the whole world with santonin if only a little attention were given to its cultivation. Digitalis leaves or preparations used to be imported in large amounts into India. It has recently been shown that the drug deteriorates during transit or storage, and that to secure an active preparation it is desirable to get fresh leaves from Indian sources. Digitalis leaves of excellent quality are now being grown in different parts of India, and the Indian drug is gradually coming into wider use.

Again, *Ephedra vulgaris* grows wild in many parts of Northern India, and recent work on this indigenous plant has led to a demand for it outside India. America alone ordered 34 tons of ephedra during 1928. Taking the minimum yield of 0·5 per cent. of ephedrine, the alkaloid extracted from 34 tons would be worth (at current prices) nearly four lakhs of rupees. Should further knowledge lead to the wider use of ephedrine in medicine India will be a rich source of the drug. In numerous other instances a little initiative would give rise to increased export and increased cultivation. The extraction of some of these drugs in local factories would probably prove more economical than the export of the crude material. Thus the manufacture of caffeine from tea-dust or of strychnine from nux-vomica seeds are examples of substances whose manufacture in India has proved economical in spite of the high cost of solvents bought from abroad. But the demand for solvents would in turn lead to other industries for their manufacture.

The Mentality of Prisoners.

Lieut.-Colonel F. A. Barker, I.M.S., Inspector-General of Prisons in the Punjab, remarks that the study of the mentality of Indian prisoners provides an untouched field for research work. Discussing the value of psychology in dealing with the gaol population, in the quarterly *Bulletin* of the Indian Association for Mental Hygiene, Colonel Barker quotes the typical instance of a prisoner now confined in one of the Punjab gaols. During his prison career he has been punished over 300 times, and owing to the exasperation caused by his conduct in the minds of his guardians he has been transferred in turn from one gaol to another until he has visited most of the prisons of the province. The only gaol administration in this country which has attempted the study of mental defectives is that of the Madras Presidency where a special gaol has been set apart for such cases at Cuddalore. The convict population of this gaol at the end of last year numbered 335, of which a large proportion were either mental defectives or recovered lunatics. The superintendent is a medical officer specially trained in mental disorders and he pays individual attention to every case. Work and discipline are both light and the irksomeness of confinement is reduced to a minimum. Apart from the advantage to the mental defectives themselves, this segregation is beneficial to the other gaols, which are relieved of the handicaps to discipline and labour occasioned by the presence of this troublesome class.

New Bombay Hospital.

Sir Leslie Wilson, the Governor of Bombay, in laying the foundation-stone of the Sir Cowasji Jehangir Ophthalmic Hospital, paid a handsome tribute to the munificence of the Parsee community. The hospital fund associated with the founder's name has reached a total of 17½ lakhs of rupees. No other equally small community in any part of the world, said Sir Leslie, could show such a proud record, and the city owed an immense debt of gratitude to those early Parsee pioneers who laid the secure foundations of the city in trade, commerce, and communications with foreign countries, and whose successors ungrudgingly poured out their acquired wealth for its benefit.

Women Surgeons for Soldiers' Wives.

Under existing military regulations, wives and families of Indian soldiers are entitled to medical attendance at their quarters by the officer in medical charge of the unit to which the man belongs, or by a subassistant surgeon. As most of the wives of Indian soldiers observe the purdah, medical officers find it difficult to see them when they are sick. It has been decided, therefore, to appoint female sub-assistant surgeons as an experimental measure, and six are to be employed, in the first place, at the more important military centres in order to give the scheme a practical trial.

EPSOM COLLEGE SANATORIUM.

SECOND LIST OF CONTRIBUTIONS.

A YEAR ago we published a description and plan of the new sanatorium which it is proposed to build to replace the present old-fashioned sick house and the temporary wooden isolation block. The plans drawn by the architects, Messrs. W. A. Pite, Son and Fairweather, showed a two-storey building, with accommodation for 50 boys, designed on the most modern system of hospital construction. The estimated cost of the sanatorium is £26,000, and as soon as £15,000 is in hand the Council of Epsom College will proceed to erect the buildings. The list of subscriptions published last year amounted to £4207 19*s.* 6*d.* Since that date the following subscriptions have been received, making a total of just over £5300.

Public Health Services.

CHANGES IN NATIONAL HEALTH INSURANCE LAW.

AMONG the changes in the law of health insurance which took effect at the beginning of the year are several of interest to the managers of hospitals. A new provision, substituted for Section 26 of the principal Act of 1924, authorises approved societies (subject to the consent of the Minister of Health) to subscribe or contribute to hospitals, dispensaries, and other charitable institutions or for the support of district nurses; such sums are to be treated as expenditure on benefits. Section 75 of the principal Act, dealing with schemes for the disposal of surpluses, is amended to allow the disposable surplus, up to such maximum amount as may be prescribed, to be applied in occasional donations to hospitals, dispensaries, charitable institutions, and district nursing funds and also "for the purposes of medical research to institutions approved by the Minister." Charitable institutions are significantly defined as any which the Minister is satisfied are ordinarily and to a substantial extent supported from sources other than public funds and payments out of funds of approved societies. Other new provisions arrange for continuing in insurance persons who cease to be employed (in place of the previous free year and prolongation arrangements), for deposit contributors, married women, and seamen. There are amendments, too, as to the management and accounts of approved societies and as to the inmates of hospitals. The 1928 Act mainly follows the Majority Report of the Royal Commission issued in February, 1926 (Cmd. 2596), but it ignores the Commission's recommendations for abolishing insurance committees and for partly pooling future surpluses of approved societies in order to finance an extension of insurance medical services. A new statutory list of "additional benefits," including dental and ophthalmic treatment, is substituted for the old list in the third schedule to the 1924 Act, and the Minister is empowered to make regulations governing the administration of schemes and of additional benefits and the arrangements for providing service or appliances towards the cost of which payment may be made by way of additional benefit. There is a modification of the conditions (contained in Section 24 of the 1924 Act) governing the administration of medical benefit. After a date to be prescribed, and except as authorised by regulations, persons (other than nurses or other hospital employees) will be restricted in respect of making their own arrangements for receiving medical treatment and attendance by way of participating in collective arrangements made through any system or institution. In this connexion it may be noted that the Minister of Health has just published new National Health Insurance (Medical Benefit) Consolidated Regulations, dated Nov. 26th, which revoke and replace the Consolidated Regulations of 1924 and seven subsequent sets of amending regulations.

This tidying process simplifying study of the regulations is in contrast to what has happened to the statutes. The Act of 1928, partly described above, sadly disturbs the neat text of the Consolidating Statute of 1924. Like the Unemployment Insurance Act of a year ago, the form of which roused Sir John Simon and Lord Carson to such vigorous protests in Parliament, the National Health Insurance Act of 1928 is an incomprehensible document in itself. The would-be student must take a copy of the principal statute and, with scissors and paste, snip out the dead matter and insert the new matter, much of which is inconspicuously presented in what the draftsman calls a Schedule of Minor Amendments. If, however, the statute book must be amended, this method of making direct alterations of specified passages is probably the simplest if the student is patient enough to work out the changes.

REPORTS OF MEDICAL OFFICERS OF HEALTH: A SURVEY OF 1927.

IN the course of last year we summarised something like a hundred annual reports of chief health officers for the year 1927, affording material for a hygienic survey of a considerable portion of the population of England, Wales, and Scotland. 1927, it may unthankfully be remembered, was a wet, cold, and sunless year.

General Sanitation.

Some progress was made in the *housing* problem, and most districts report that there is now accommodation available for the artisan and higher-paid worker, if he is willing to pay a higher rent. There is still little chance for the poorest workers and the big families. A few districts have done something in the matter of slum clearance. We are, in fact, just reaching the greatest difficulty of the problem—viz., the clearance of the slums and the provision of

houses for those who cannot pay the rentals which have to be charged for municipal houses.

There are many complaints as to the want of control of building. Houses may be erected where there are no drains and no roads for access. "Ribbon building" along the arterial roads is frequently inharmonious and destroys the beauty of the countryside. Suggestions have been made that new houses in the country should be built in clusters off the main roads.

In some districts renovation is carried out successfully in the default of the owners. In others the houses are too old and worn out for this treatment. Several medical officers favour Octavia Hill methods; others would like to see more effort to adapt municipal houses to the size of the family, so as to avoid subletting. One suggestion, to meet the wants of those most in need, is that some of the municipal houses should be let by the Health Committee with regard to the requirements and capacity to pay of the tenants, while the bulk are let on more or less business lines by the Housing Committee. From several districts come complaints as to the nuisance from tents, vans, sheds, and other makeshift houses.

The Housing (Rural Workers) Act, 1926, has been welcomed by many county medical officers, but the work done during the last half of 1927 was largely preliminary.

Scavenging.—New salvage schemes have in some cases caused adverse comments as to the handwork involved. In some districts there is also a difference of opinion between the medical officer and the surveyor as to the suitability of the maxim, "Burn your own refuse," seeing that house fires are not adapted for the purpose like the furnaces of a destructor.

Water-supply.—Many of the country districts are unsatisfactorily supplied, especially in the dairying counties. The need for some system of national pooling is obvious.

Smoke Prevention.—The new Act is being taken seriously, and has undoubtedly stirred up interest. Regional smoke advisory committees are in the air, and at least one executive committee has been formed—for Sheffield and Rotherham. More consideration is being given to smokeless fuel. Glasgow, Salford, and Halifax, amongst others, have paid special attention to this matter. In nearly 2000 of the Hull municipal houses the "Cookanheat" apparatus has been installed.

Rivers pollution is still in an unsatisfactory position. Notts reports great benefit from the appointment of a whole-time inspector, and that the trades are beginning to take a hand by instigating research. Ultimately no doubt this matter will be taken up by Boards for each river with all its tributaries. One can hardly expect the ratepayers of one county to go to great expense in purifying their rivers in order that the water may be fit for a neighbouring county to drink.

Milk.—The English counties have not, as a rule, instituted veterinary inspection of dairy cows but content themselves with following up tuberculous milk samples, often with very limited success in the discovery of the offending cows. There is no evidence of any lessening of bovine tuberculosis as judged by milk sampling or meat inspection. The Durham County Council have arranged for a scheme of inspection by whole-time veterinary surgeons. Clean milk competitions increase in number and do something to teach the employees, even the older ones, new and cleaner methods. Complaints of bottling milk in the street are quite common, and there is great need reported of a simpler nomenclature for graded milk. A noteworthy matter is the very varying percentage of tuberculous udders found in those towns where regular veterinary inspection of milk herds is in force.

Meat.—From the London meat markets comes an interesting report as to the discovery of bacilli of the avian type in tuberculous pig carcasses. Some 30 per cent. of the specimens examined by Dr. Stanley Griffith and Mr. R. L. Cornell, M.R.C.V.S., were found to be of the avian type, indicating that precautions should be taken to prevent pigs from feeding with infected fowls.

Infectious and other Diseases.

Diphtheria.—Immunisation is being generally adopted for hospital staffs and also for stemming outbreaks in schools and residential institutions. Edinburgh, several London boroughs, and Walsall are using it for the protection of the children generally. The city and county of Aberdeen immunise against both diphtheria and scarlet fever simultaneously on a considerable scale. The virulence test is being more generally adopted in order to set harmless carriers free from restrictions.

Scarlet fever is, as a rule, so mild as not to justify the expense of isolation in hospital, but in Bootle a great increase in severity was noted. Antitoxin for severe cases is becoming generally used, and in a few cases the hospital staffs are immunised.

Small-pox of the mild type has been prevalent in many districts. The few deaths attributed to it have mostly been those of persons suffering from other diseases.

Influenza was very prevalent in the first quarter of the year and swelled the death-rate from respiratory diseases in most districts. Glasgow was an exception and had less influenza than in 1926.

Poliomyelitis was less in evidence than in the previous year but caused a considerable outbreak in Hull with some evidence of case-to-case infection.

Encephalitis lethargica gave rise to fewer notifications but had a higher fatality-rate. Sometimes the deaths equalled or exceeded the notifications.

Rheumatism in Children.—Paddington and Kensington both inaugurated supervisory schemes with compulsory notification. Birmingham and the West Country are also taking up this subject with energy. Bristol has a scheme. Cardiff has been presented with a building, which is to be used as a rheumatism supervisory centre, while Plymouth has a "rheumatism register."

Tubercle.—The lateness of notification is a general complaint, and Salford and Newcastle are among the districts which cannot fill their sanatoriums with early cases. Belief in the efficacy of artificial pneumothorax in selected cases is growing.

Cancer.—Leicester has established a diagnosis clinic at the Royal Infirmary. Several local committees are active, and Manchester reports hopeful research as to the cause of "mule-spinners'" cancer.

Maternity and Child Welfare.

In several districts the newly trained midwives coöperate well in sending their cases to antenatal clinics. It is being more generally recognised that experienced obstetricians are required for the successful conduct of antenatal clinics. During the year Derbyshire made a new appointment of a whole-time woman doctor with special experience in obstetrics and gynæcology to conduct antenatal clinics, supervise and lecture to the midwives, &c. Several districts have followed the example of Hampshire in starting insurance schemes to secure the help of a doctor when needed by the midwife. A very general complaint in the reports is that the pay and status of the midwives are quite inadequate. One large Birmingham firm has arranged that "home helps" may be sent to the homes of their workpeople during the confinement or non-infectious illness of the mother, and has guaranteed the full fee in every case.

Hospitals.

There are many reports of the want of beds in general hospitals. Aberdeen has led the way by absorbing the poor-law hospitals. Many other towns have secured beds in the poor-law hospitals by coöperation with the guardians—e.g., Kensington, Glasgow, Sheffield, Leeds, Reading. The need for hospital treatment of pneumonia is being recognised on all hands. Many county medical officers complain

of the slow progress made in pooling the isolation hospital accommodation in these days when increased transport facilities make it desirable.

Artificial light treatment is being taken up in an increasing number of districts, but the reports vary much as to the benefits obtained.

Health Education of the Public.

This aspect of public health work is exciting more interest, and some novel methods are reported. Thus Plymouth has a Runsyne machine with an illuminated message fixed at a tram terminus, while Salford has window displays at the health office. The Bootle M.O.H. mentions that Merseyside has adopted a joint programme with a whole-time medical lecturer and organiser, but complains that the Ministry do not pay a grant towards the maternity and child welfare and tuberculosis portions of the work.

A REVIEW OF SCHOOL MEDICINE IN 1927.

THE year 1927, judging from the reports [1] of school medical officers, showed considerable advance in school medicine, though it was retarded by the general financial restriction. Closer coöperation was established between the school service and the general public health work, especially that of the infant welfare centres. The medical officer for Swindon remarks that each year it becomes more anomalous to describe the health of the school child separately from that of the general population. Most of the defects and diseases found in school-children arise during pre-school years, and school entrants who have previously attended infant welfare centres have fewer defects than other children.

Coöperation is assisted by having a medical officer working partly at the welfare centre and partly at the school, by having the cards of the welfare centre sent on to the school when the infant becomes an entrant, by making the dental, aural, orthopædic, and other school clinics available for infants, and by the establishment of nursery schools such as those in London, Manchester, and Bradford. At Leeds and in Leicestershire a comparison has been made between the condition of infants who had suffered from the exanthemata and those who had escaped, with the result, somewhat surprising at first sight, that the difference was slight, and such as it was seemed to suggest that attacks of measles and the like actually reduce the tendency to defects in later childhood. This result may be a tribute to the care now spent on infantile ailments. In many areas a feature of the year has been the inauguration of an orthopædic scheme, including the appointment of a consultant surgeon and the establishment of an orthopædic clinic. Often, too, specially trained orthopædic nurses have been appointed to give massage and electrical treatment in the clinics, or as in Cumberland to visit the homes. Coöperating in this work are also voluntary agencies such as the "Tiny Tims" Clinic at Eastbourne or the Cripples Society at Bristol. Another adjunct is the special school for physically defective children and the open-air school. In the preventive work of correcting and guarding against minor deformities much help is given both at the remedial exercises clinic and (in a wide view) by most of the beneficent activities of the organisers of physical training, and it is appropriate that the practice is spreading of including their reports in one volume with that of the school medical officer.

Coördination in orthopædic work is well seen in Hull, where the victims of an epidemic of poliomyelitis were treated in the City Hospital, seen by the consulting orthopædic surgeon, while splints were fitted at the physical defectives school, remedial exercises and massage given at the orthopædic clinic, and a further example of coöperation lies in the fact that in the case of private patients the special facilities at the clinic were offered to the family doctors, and in the great majority of cases accepted. Open-air schools are giving extended proof of their value wherever they are established; notably favourable factors exist at Torquay and Eastbourne. In some of the great industrial cities there is still delay in meeting an urgent need. Dental work is almost everywhere spreading, consolidating, and organising. At Leeds and Stockport, for instance, one feature of progress is an attempt to eliminate the "casual" cases, that is those who only come for treatment when symptoms like toothache are urgent, and to devote more attention to regular and conservative work. In scattered areas like Cumberland a dental van has been found of value. In some areas dental propaganda, better called dental education, is being vigorously carried on. At Cambridge this has gone on to lectures and examinations for elder girls with excellent results.

A pleasing circumstance is the growing appreciation by the school medical officer of the coöperation and help of general practitioners in securing for school-children prompt treatment of their ailments. At Sheffield this applies to the facilities offered for the X ray treatment of ringworm. At Hull it is the orthopædic clinic; at Bristol it is the rheumatic clinic where it is stated that the response of medical practitioners is admirable. Words such as these may be set against what has been called the encroachment of public health enterprise on private medical work. If inroads have been made on the work and earning capacity of the private practitioner their locus has been for the most part that no-man's land of conditions for which treatment was not hitherto generally available—e.g., refraction of the eye and X rays. There is some truth, too, in the statement that the work of welfare centres and school doctors has attracted the attention of parents to the health of their children, and has thus led them to seek private medical advice more frequently. However this may be, it must be remembered that the private practitioners form the backbone of the profession, so that friction between them and their colleagues in the public health service would be disastrous.

The rheumatic clinics prominent in Bristol and in London, where there is increasing hospital accommodation, are of great importance in preventing invalidity, loss of working time, and premature death in later life.

[1] See THE LANCET, 1928, ii., 37, 93, 328, 501, 1147, 1311.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 22ND, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 201 (last week 176); scarlet fever, 2451; diphtheria, 1350; enteric fever, 31; pneumonia, 1481; puerperal fever, 43; puerperal pyrexia, 95; cerebro-spinal fever, 2; acute poliomyelitis, 3; encephalitis lethargica, 22; dysentery, 11; ophthalmia neonatorum, 108. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified in the following 16 counties: London, 6 (Battersea 1, Lambeth 4, Poplar 1); Chester, 3 (Ellesmere Port and Whitby); Derby, 23; Durham, 34 (of these, South Shields 11, Jarrow 14); Essex, 13 (East Ham 4, West Ham 9); Huntingdon, 1 (Old Fletton); Lancaster, 15 (of these, Oswaldtwistle 11); Leicester, 13 (county borough); Northumberland, 21 (Tynemouth); Nottingham, 6; Soke of Peterborough, 3; Stafford, 4; Warwick, 1 (Coventry); Yorks, West Riding, 33 (of these, Halifax 25); Glamorgan, 17; Monmouth, 8.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Dec. 25th–26th was as follows: Small-pox, under treatment 17, under observation 2; scarlet fever, 2130; diphtheria, 2098; enteric fever, 16; measles, 44; whooping-cough, 466; puerperal fever, 19 (plus 5 babies); encephalitis lethargica, 73; poliomyelitis, 5; "other diseases," 21. At St. Margaret's Hospital there were 8 babies (plus 1 mother) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was no death from small-pox, 7 (0) from enteric fever, 21 (0) from measles, 7 (0) from scarlet

fever, 52 (12) from whooping-cough, 42 (10) from diphtheria, 65 (13) from diarrhœa and enteritis under two years, and 69 (9) from influenza. The figures in parentheses are those for London itself.

No death occurred from enteric fever, measles, or scarlet fever in London. The fatal cases of enteric fever outside London were reported from Stoke-on-Trent 2, Exeter, West Bromwich, Wallasey, Sunderland, and South Shields 1 each. Stockton-on-Tees and Newcastle-on-Tyne each reported 4 fatal cases of measles, Liverpool and Hull 3 each. (Belfast 7.) Whooping-cough was most fatal in Salford with 6 deaths, Manchester with 4, Plymouth, Warrington, and Leeds with 3 each. Salford reported 6 deaths from diarrhœa, Liverpool and Manchester 5 each, Birmingham 4. The reported deaths from influenza are fewer, but Manchester notified 9.

The number of stillbirths registered during the week in the great towns was 265 (corresponding to a rate of 41 per 1000 births), including 37 in London.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. W. N. L. Cherry is placed on the Retd. List with rank of Surg. Capt.

Surg. Lt.-Comdr. K. A. I. Mackenzie to be Surg. Comdr.

Surg. Lt. P. J. A. The O'Rourke to be Surg. Lt. Comdr.

J. M. McNamara and M. J. Brosnan to be Surg. Lts.

The following appointments are notified :—Surg. Comdrs. : A. C. V. Green and J. M. Hayes to *Victory*, for Haslar Hospl. ; T. R. L. Jones to *Benbow* : and S. W. Grimwade to *Emperor of India*.

ROYAL NAVAL VOLUNTEER RESERVE.

H. H. Bailey to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Maj. L. A. A. Andrews, half-pay list, retires on retd. pay on account of ill-health, and is granted the rank of Lt.-Col.

Maj. C. Russell, from R.A.M.C., Res. of Off., to be Capt.

TERRITORIAL ARMY.

Maj. H. L. Garson to be Lt.-Col., and to comd. the 170th Cav. Fd. Amb.

Capt. H. G. L. Haynes to be Maj.

Capt. A. L. Crockford (late Gloster R.) to be Lt., and relinquishes the rank of Capt.

Lt. J. R. McDonald to be Capt.

F. A. Bevan to be Lt.

INDIAN MEDICAL SERVICE.

Col. C. Hudson to be Maj.-Gen.

Lt.-Col. S. R. Godkin to be Col.

Temp. Lts. to be Temp. Capts. : Rochiram Udhamdas Hingorani, Janardan Madhav Gole, Cheruvari Kottieth Lakshmanan, and Kundan Lall Jetley.

To be Temp. Lts. : Taqiud Deen Ahmed, Muhammad Jafar, Girdhari Lal Kohli, Bawa Harnam Singh, Ved Vias Puri, and Ellamana Siva Rama Menon.

Lt. Surendra Nath Lahiri resigns his commn.

DEATHS IN THE SERVICES.

Col. Peter Broome Giles, C.B., who died at Folkestone on Dec. 19th last, aged 62, qualified with the M.R.C.S. Eng. in 1871, taking the L.R.C.P. Edin. in the following year. In 1897 he obtained the F.R.C.S. Edin. For a time he was in private practice in Herefordshire, and subsequently went to Buckinghamshire, of which county he was High Sheriff in 1907. He was a J.P. for both counties as well as for Folkestone. Always a keen Volunteer he joined the Artists' Rifles, and later, when attached to the Hereford Volunteers, raised the Welsh Border Bearer Company. On the formation of the Territorial Force he was promoted to the rank of Colonel and was appointed A.D.M.S. to the 1st London Division in 1908. During the war he was Commandant of the Military Convalescent Hospital at Alnwick and afterwards at Ashton-in-Makefield, when he was severely wounded in an air raid. Col. Giles, who was created C.B. in 1911, was a County Director of the City of London Branch of the British Red Cross Society, and held the Volunteer and Territorial Force Decorations. He married, in 1879, Florence, daughter of the late J. C. Houghton, of Quinta Brobury, Hereford, and of London, who, with one son and one daughter, survives him.

"Audi alteram partem."

SOME ASPECTS OF DENTAL SEPSIS.

To the Editor of THE LANCET.

SIR,—Dr. Tallent Nuthall in his interesting paper under this heading in your issue of Dec. 22nd, 1928, writes of the "dead tooth heresy" and states that it is a common thing for radiographic reports to lay stress on the vitality of teeth to the exclusion of other points in attempting to estimate the degree of dental sepsis present. I would suggest that in reality there is no heresy, and that any apparent confusion of thought on this particular point exists among those radiologists who so confidently pronounce a verdict on the strength of a set of films or those doctors who so implicitly accept such reports and pass sentence on the teeth accordingly. A competent dentist will only give an opinion on the presence or not of dental sepsis after a consideration of *all* data, of which the radiological is only a part, and not always the most important part. He may often find it very difficult to decide whether there is any sign of infection, and still more, whether teeth should be saved or extracted, but if he knows his pathology he will not have any difficulty in estimating correctly the significance of the pulpless tooth.

As Dr. Nuthall truly states, there are two main forms of dental sepsis : pyorrhœa alveolaris, in which the infection starts at the gum-margin and extends deeply into the bone, and apical infection, in which the infection follows death of the pulp and, passing through the apical foramen, infects the periapical bone. In the first form, pyorrhœa, the dental tissue affected is the periodontal membrane. The pulp, though it may early show signs of degeneration, may remain alive until a late stage of the disease. The gravity of pyorrhœa is estimated by the depth of the pocket, the presence of pus, and, radiographically, by the bony changes. The question whether the pulp is dead or alive has little bearing on the problem of treatment. It is obvious that a pyorrhœic tooth which is also dead has lost so much of its nutrition that its life in any case is limited, but since the majority of the teeth in pyorrhœa are actually vital the decision as to the treatment must be decided primarily by a consideration of the bony changes. Those who would extract dead teeth only (it is inconceivable that there should be dentists among them) would therefore ignore pyorrhœa as a cause of dental sepsis, a reductio ad absurdum !

In the second form of dental sepsis, apical infection, the actual path of the infection postulates the death of the pulp. If it is vital (with rare exceptions which cannot be considered within the limits of a letter) then apical signs in a radiogram will be absent. Those who advocate procedure 4 (see Dr. Nuthall's letter) must equally advocate procedures 2 and 3. What I suppose Dr. Nuthall *may* mean is that a certain school of thought, which has found its most vocal expression in America, has advocated the extraction of all pulpless teeth as a routine measure irrespective of whether they show radiographic change or not on the grounds that they may be infected without radiographic signs, or if not infected they may become so later, and in any case they are pestilent fellows better out of the mouth. This is, indeed, a crude and unscientific procedure which has happily not found much support in this country. It is by no means clear to my mind that Dr. Nuthall is referring to this school, and since his paper may be misconstrued and appears to exhibit some confusion of thought on the pathology of dental sepsis, it appears desirable to make clear that he is really flogging a dead horse, for everyone should know that in pyorrhœa the vitality of the teeth is a minor matter and in apical infection death of the pulp is so necessarily

antecedent to the apical changes that we can take it for granted.

We sadly need accurate criteria as to the indications which demand extraction of teeth because of some general condition, for it must be a distressing reflection to every conscientious dentist that when he decides to extract teeth not in themselves painful and often highly functional he is in effect carrying out a clinical experiment on his patient which involves a mutilating operation, and may frequently fail to improve the general or local condition for which the extraction was prescribed.

I am, Sir, yours faithfully

Brook-street, W., Dec. 28th, 1928. A. T. PITTS.

ASTHMA RESEARCH COUNCIL.

A NATIONAL APPEAL FOR FUNDS.

To the Editor of THE LANCET.

SIR,—In March of last year you were good enough to publish (THE LANCET, 1928, i., 561) the scheme of investigation and research proposed by the Medical Advisory Committee, to be carried out when the financial support of the Asthma Research Council permitted. During the last nine months this Committee has obtained the coöperation of many physicians in the provinces and the consent of their local hospitals to the formation of research centres, when these can be financed by the Council. By means of grants made by the Halley Stewart Trust and the Medical Research Council an asthma clinic and research centre has already been formed at Guy's Hospital to continue Dr. G. H. Oriel's investigation into the biochemical causation and treatment of asthma, and to supplement and control the results of such treatment by comparing them with those obtained by other methods. A second grant by the Halley Stewart Trust has been given for the study of the characteristics of asthma occurring in childhood; and a special clinic is now being organised at Great Ormond-street Hospital to carry out this work. A research Fellow, endowed by the British Humane Association, has already visited many continental spas and is now investigating the results of the physico-therapy methods there employed by means of apparatus installed by that Association. In order to obtain fuller statistics concerning hereditary influences on this disease and on the general asthma syndrome, family history forms have been approved and printed. They can be obtained from the medical secretary; and the Medical Advisory Committee trusts that medical men will assist the inquiry by circulating them among suitable asthmatic patients. The Asthma Research Council itself, having meanwhile been strengthened and reorganised, will inaugurate a national appeal for funds at a Mansion House meeting at 3 P.M. on Jan. 15th. The Lord Mayor will preside and Sir Humphry Rolleston, Dr. A. F. Hurst, Colonel F. E. Fremantle, M.P., and Mr. Ben Tillett, among others, will speak. The attendance of medical men will be much appreciated.

The Council desires to raise a sum of £50,000, and donations should be forwarded to the Hon. Treasurer at the Council's office.

The personnel of the Medical Advisory Committee is as follows: Dr. A. F. Hurst (Chairman), Prof. R. J. S. McDowall (Vice-Chairman), Dr. H. W. Barber, Dr. L. S. T. Burrell, Dr. E. A. Cockayne, Dr. John Freeman, Dr. R. D. Gillespie, Mr. V. E. Negus, Dr. S. Gilbert Scott (London); Dr. James Adam (Glasgow); Dr. John Hay (Liverpool); Sir Thomas Houston (Belfast); Dr. W. E. Hume (Newcastle); Dr. R. Cranston Low (Edinburgh); Dr. J. A. Nixon (Bristol); Dr. F. E. Tylecote (Manchester); Dr. G. W. Watson (Leeds); Dr. W. H. Wynn (Birmingham).

I am, Sir, yours faithfully,

T. T. JEANS,
Surgeon Rear-Admiral (ret.), Secretary, Medical Advisory Committee.
Asthma Research Council, 42, Ranelagh-road, S.W.,
Jan. 1st, 1929.

RESTRICTED DIETS OR INSULIN?

To the Editor of THE LANCET.

SIR,—The strong influence of American authors upon our outlook on diabetes has somewhat overshadowed the work on this subject being done in Germany and Austria. It may be worth while, therefore, to call attention to the views of Prof. Wilhelm Falta, of Vienna, some of which he has recently summarised.* During more than three months spent in Vienna as Radcliffe Travelling Fellow I have had the chance of studying these methods to some extent and of comparing them with our own, and it is a great pleasure to be able, with Prof. Falta's permission, to review briefly some features of his important work.

Prof. Falta—to whom we owe the introduction of the "Mehl-Früchte-Tage"—bases his treatment of diabetes upon this fundamental object—to give back to the diabetic patient the active, happy, *unrestricted* life of a normal individual. From this follows the simple principle that "insulin should be given whenever we are unable to maintain the nutrition and the bodily and mental activities at a *normal* level without it"; and further, "by means of insulin treatment of diabetes, all extreme forms of diet have become unnecessary, and in general a diet should be given of normal composition in which the individual peculiarities of the patient can be readily allowed for." He thus believes that a diabetic should be dieted like a normal individual and considers that insulin treatment offers us a perfect form of substitution therapy.

Such views are, of course, in direct opposition to those of many authorities, notably of Joslin[1] in America, and in the main to the methods at present employed in England. These methods are based on a belief that the diabetic organism is at fault in more ways than in merely having an inefficient insulin mechanism, and that under all circumstances the patient's diet should be to some extent restricted. The assimilative power of the diabetic organism is supposed to be limited not only in respect of carbohydrate (preformed or potential), but also in respect of total calories as such; and it is believed that any harmfulness of excessive food, especially fat, in diabetes (Joslin) consists pre-eminently in an overload of the total metabolism.

At the same time attention is perhaps too often directed to the disease rather than to the patient. Even should the views of Joslin,[1] Rabinowitch,[2] and others be confirmed, that high diets in diabetes, —though covered with sufficient insulin dosage— exercise a detrimental effect upon the disease, we must, nevertheless, consider whether happiness is not so important to the patient that it should govern our treatment, even at the expense of a possible adverse effect upon the progress of the condition. The psychological effect of constant attention to a restricted diet—an extreme "Minderwertigkeitsgefühl"—is too little regarded, and only too often neglected. If we can restore a normal existence to our patient, and give him the satisfaction of feeling that he is once more a useful member of society, we confer upon him not only a benefit of immense value, but at the same time remove the unfavourable influence that depression, worry, and unhappiness have been shown to exert in diabetes. This has been amply demonstrated by Falta, and the altered mental outlook of the diabetics under his treatment in Vienna is perhaps the most striking impression left after a study of the patients under his care.

The cautions so often urged against giving increased diets with the aid of insulin should especially apply to the diabetes of children. It is in the young, however, that Falta's results are most remarkable, for under

* Neue Probleme des Diabetes Mellitus, Wien. Med. Woch., 1928, lxxviii., 1131 and 1162.

[2] Rabinowitch, I. M.: Quart. Jour. Med., 1928, xxi., 211.

his régime bodily and mental development proceed as well as in healthy subjects.

For the details of his methods his original papers must be consulted. The chief essential is "schooling of the patient," who must be educated to manage his own diet and taught that his insulin requirements are exactly dependent upon the carbohydrate and protein content of his food. He must know that severe exercise lowers his need for insulin, and that on the first symptom of hypoglycæmia sugar must be taken; he must know that his insulin demand can vary and will lessen with anything that decreases his intake or absorption (e.g., gastro-intestinal disorders); he must be instructed to test his own urine and to increase his dose of insulin when sugar appears. He must be taught, in fact, almost to become his own doctor, though the ultimate control must, of course, remain in experienced hands. That this can be achieved, even with the most poorly educated patients, has been fully demonstrated at Prof. Falta's hospital clinic. Carbohydrate is allowed to about the equivalent of 8 oz. of bread (i.e., 160 g. carbohydrate), and protein to about 100 g., and fats are taken in the amounts that a normal individual would himself choose. "It is purely technical difficulties that prevent me from giving 300 to 400 g. of carbohydrate, although 200 g. of bread-equivalent are in fact sufficient," writes Falta, "and I know of no single reason which under ordinary circumstances should cause us to depart from the dietetic principles applicable to normal man; in fact, every departure has its disadvantage; and though complications may demand variation at times, I aim as soon as possible at a normal diet." Investigations over a long period have convinced him that restricted diets are inefficient, and that removal of sugar and acetone by dietetic means is too often bought at an excessive price. The one-sided diets, such as Petrén's vegetable and fat diet, he regards as unnecessary and often impracticable, and the restriction of carbohydrate and ordering of fast-days—still so firmly advised, despite the introduction of insulin—are, in his opinion, errors of treatment based purely upon theoretical considerations. Fast-days merely upset the insulin dosage, and lower diets limit the bodily nutrition and thus the capacity for exertion. No procedure that threatens the state of nutrition is permitted, and exercise with its beneficial effects upon the sugar tolerance is in every way encouraged. Falta's careful investigations have shown that variations between 100 and 200 g. of fat do not cause any change in the insulin requirements of the diabetic or the output of sugar in his urine, and the work of Widmas,[3] who has emphasised the value of high caloric diets and the negligible influence of fats upon the blood-sugar, supports this view. Thus, with sufficient carbohydrate in the diet, and corresponding dosage of insulin, very large amounts of fat may be utilised without formation of ketone bodies, and man's natural regulator—the appetite—may be allowed to control his caloric intake. Joslin's view that the safest quantity of fat for the diabetic is as little above 50 to 100 g. as possible, must, in the face of Falta's results, be seriously questioned (compare also the work of Wagner [4]).

Adequate insulin dosage may restore efficiency to the islet organ as rest may restore it to the decompensated heart; in cases of acute overstrain of the carbohydrate mechanism ("Ueberlastung und Erschöpfung") such return of function may occur. In some cases, however, the insulin requirements gradually increase (progressive cases); in others they remain for many years stationary. Therefore, the patient's question, whether if he once starts insulin he will ever be able to leave it off, can only be answered with the lapse of time. That actual regeneration of the Langerhan's cells takes place—as some animal experiments lead us to suppose (Herring [5]; also Boyd and Robinson [6])—Falta thinks to be in some cases highly probable. Thus tolerance will often surprisingly improve under his régime, and the increasing good health of his patients, combined with systematic muscular exercises, is often accompanied by much diminished insulin requirements. When the dose, however, has to be raised to 80 or 90 units daily to cover his standard diet, containing approximately 160 g. of carbohydrates, it is thought to represent substitution for a completely degenerate and functionless islet organ, and there can be little hope of any lessening in the need for insulin. Temporary so-called insulin-resistant cases due to increased irritability of the nervous system, or to complicating infectious disease, may also, of course, require equally high dosage.

Falta has thus shown that by a rational nutrition with insulin everything can be attained that is demanded from a substitution-therapy. That his results have justified his technique is amply demonstrated by his patients. Expensive, one-sided, and troublesome diets, which are often almost impossible to maintain in ordinary society, are for the patient abolished, and for the doctor a constant and wearying process of dietetic calculations is replaced by a short period of interesting instruction. The treatment of the diabetic lies with the patient, in his own hands and in his own home. It must, however, be emphasised that superior medical control is essential, and that no tendency to over-indulgence in food or to abandonment of due care by the patient or doctor is in any way suggested.

I am, Sir, yours faithfully,

MEDICAL FOUNDATIONS:

A PLEA TO TESTATORS.

To the Editor of THE LANCET.

SIR,—During 1928 I have seen in the press particulars of the wills of fully ten or a dozen medical practitioners who obviously, from the details given, had no dependants. Large sums were bequeathed to various deserving charities, but nothing at all to those charities which should have the first call on members of the profession—that is, Epsom College and the Royal Medical Benevolent Fund.

The bulk of us, of course, have to think first of our families when making a will, but to those who have none, I urge the duty of preference to the proper charities of our own profession. At Epsom College the Council are engaged on the uphill task of collecting money to build a new sanatorium. After a year and a half of effort about one-fifth of the large sum required has been obtained. A few good legacies would enable a start to be made with this most necessary improvement: a fortiori, from those who can afford them, immediate contributions of any size will be most gratefully accepted.

I am, Sir, yours faithfully,

HENRY ROBINSON.

Bramham-gardens, S.W., Dec. 30th, 1928.

SURGICAL ACCESS TO THE BRAIN.

To the Editor of THE LANCET.

SIR,—In your issue of Dec. 8th, 1928, we find on page 1193 an editorial on Surgical Access to the Brain, in which you seem to make a sweeping statement that up to and until the present there has not been a satisfactory means of access to the brain. We therefore enclose to you a bulletin showing the Albee electrically operated instruments which, we believe, are recognised through the world as the most advantageous appliance for this work available, as many of them are sold throughout Great Britain, in fact throughout the world. Thousands of them are in use in America.

On page 1177 of the same issue, Mr. W. H. Ogilvie speaks of the apparatus available previous to his

invention as expensive in first cost and in repairs. Neither statement applies to the Albee outfit. The Albee outfit is not cumbersome, the sterilisation is eminently satisfactory, the leads need not be draped in towels because they are sterilisable, and the Albee perpendicular saw permits of access to recessed bones much better than the drill illustrated in Fig. 2A (page 1178).

In justice to Dr. Fred A. Albee, a New York City surgeon of international reputation, as well as to ourselves who manufacture the Albee instrument exclusively, we feel a correction of these statements is due. We are, Sir, yours faithfully,

THE KNY-SCHEERER CORPORATION OF AMERICA.

Dec. 21st, 1928.

*** We can find no such statement in the leading article. It is expressly stated that there is now on the market, for opening the skull, excellent electrically driven apparatus, which can be sterilised and the speed of which can be readily controlled.—ED. L.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LOCAL GOVERNMENT BILL.

(*Continued from p. 1364 of last issue.*)

ON Tuesday, Dec. 18th, 1928, the House of Commons went into Committee on the Local Government Bill, Captain BOURNE was in the chair. This was the third allotted day under the guillotine resolution.

Clause 13 provides that as from the appointed day it shall be the duty of every county council and county borough council and other local authority to recover from any person who has been maintained by them in any hospital, maternity home, or other residential institution in which accommodation is provided by the council, other than a person who had become an inmate of an institution for the purpose of receiving treatment for infectious disease, or from any person legally liable to maintain that person, the whole of the expenses or such part as the council are satisfied they can pay.

Recovery of Cost of Treatment.

Mr. SIDNEY WEBB moved to omit the words "it shall be the duty of," which made it obligatory on the council to present the Bill for the full amount. He said that that full amount as the clause stood appeared to include the whole cost of all the medical treatment, however expensive that might be. The North Middlesex Hospital, which was under the administration of the Edmonton Board of Guardians, had just obtained the sanction of the Minister of Health for an expenditure of £6000 on radium to bring its equipment up to date. It was better equipped in many respects than a good many voluntary hospitals. The practice there was to recover from the patients as much as the board of guardians thought it could recover up to the total limit of cost, and in that connexion no question arose. The total cost last year was 49*s.* a patient per week. If the institution was handed over to the Middlesex County Council, as it would be, it would mean that the Act would require the county council to present a bill of 49*s.* a week to every patient who used the institution, although in the case of the board of guardians only about 15 per cent. of the patients paid any contribution, and in 85 per cent. practically nothing was recovered. It would be a very serious change to make if, instead of preventing a bill for 5*s.*, 10*s.*, or 20*s.* up to 49*s.*, according to the means of the person in only 15 per cent. of the cases, the local authority should be required to make the full charge of 49*s.* in all cases. If everyone who went into that hospital was told that he or she would receive a bill necessarily at the rate of 49*s.* a week, without some prospect of the amount being reduced, it would be, he was informed by medical people concerned, a very serious deterrent to people going into that hospital at the earliest possible date. A ward was being fitted up with radium at very great expense for the treatment of cancer. Now every poor woman for whose benefit this was being done would be told that she would be presented with a bill for 49*s.* a week if she went into that hospital. That could not fail to be a very deterrent effect on the use of the hospital. It would not be in accordance with the Minister of Health's intentions or desire to make the emphatic change, and to insist that instead of the bill being graduated according to the patient's means the full amount in each case would have to be presented.

Mr. PETHICK-LAWRENCE, who seconded the amendment, drew the attention of the Minister to the case of the unmarried mother. He said that at present whether the unmarried mother was treated in a voluntary hospital, a special nursing home, or in an institution under a local authority, great care was taken to preserve the secrecy which might be necessary in these cases. Under the clause, however, if the woman herself was unable to produce any money, application would be made at once to members of her family—her father, or whoever might be responsible in law for her. The result of that would be that these women would not go into a home or institution to be treated. To-day it was recognised that it was folly not to help people to fight against infections and venereal disease. Could it be suggested that in regard to cancer and maternity and child welfare the position was different ?

Mr. CHAMBERLAIN said that if the amendment were carried they would be exactly where they were at present. Local authorities already had this power. There was nothing in the Bill which said, as Mr. Webb suggested, that the local authority must present a bill for the whole of the expense to a person receiving treatment. It was not contemplated that the local authority should do anything of the kind. They would do precisely what was done now in other cases. They would, through their officers, find out whether a person was able to pay anything, and, if so, how much, and they would make those inquiries before sending in their bill. The object of the clause was to have one rule for both kinds of institutions. If there was not a provision of this sort, the position would be that in the case of a destitute person treated under the poor-law it would be the duty of the local authority to recover the whole of the costs from him, or such part as he was able to pay, but in the case of a person who was not destitute, and was able to pay, there would be a discretion with the local authority. That was a very topsy-turvey state of things, and an anomaly which was being removed by this clause.

Mr. A. GREENWOOD, in supporting the amendment, said that the clause would mean that some of the energy and time of the administration staffs of the public departments would be diverted to the business of collecting money. The Opposition did not so much regard the mere collection of the money as obnoxious, but they thought that the new duty which was imposed on local authorities was bound to be a deterrent, and would lead to numbers of people who ought at an early stage to seek institutional treatment to postpone it or not to go at all.

Dr. VERNON DAVIES said that Mr. Greenwood showed extreme lack of knowledge of the subject on which he had been speaking. Perhaps the hon. Member would allow him (Dr. Davies) as an old medical officer of the poor-law, as a hospital official, and as a general practitioner, to let him know what really happened. In the majority of cases a person who was sick went first of all to his private doctor without any thought of what it was going to cost. The doctor examined him, and if the case required treatment in an institution he sent the man to the institution. In some of the large towns they would find, occasionally, that the patients, instead of going to a doctor, went to the out-patients' department of a voluntary hospital and got some attention there, without any cost at all to themselves. For Mr. Greenwood to say that the Government by this Bill were trying to prevent people seeking medical assistance at the earliest possible moment was to say what was not true, and to put a false construction on the Bill. The people of this country had known for years that they could always get medical assistance either from hospitals, poor-law institutions, or from doctors without any thought of the ultimate cost. Let them take the case of a general practitioner in an industrial district—in the huge majority of cases. That doctor did not ask a patient: "Where is your fee, and then I will tell you what is the matter with you." (Labour cries of "Oh!") Labour Members might speak from rumour or hearsay, but their attitude was a distinct reflection and libel on a most honourable profession. He maintained without fear of contradiction that no man or woman in this country need delay for one moment in getting the most expert advice and the most expert treatment through fear of poverty, or of the cost, and there was nothing in the Bill which would hinder them in the slightest degree. It was absolutely wrong for an hon. Member on the Opposition front bench (Mr. Greenwood) to make the statements which they had heard that afternoon, but he asked hon. Members and the people of the country to notice that this was the policy of the Labour Party, and that the destitute poor should be charged for medical attention but that the public health authorities need not make a charge. They were asking for this—to charge the destitute poor, but not to allow the public authority to do so—and that was a scandal.

After further debate, the amendment was rejected by 236 votes to 130.

(*To be concluded.*)

Obituary.

DAWSON FYERS DUCKWORTH TURNER, M.D., F.R.C.P., F.R.S. EDIN.

Dr. Dawson Turner, who died at Godalming on Christmas Day, was one of the pioneers of radiology in this country. His influence on its development was considerable, and though an original and inquiring mind went far towards fitting him for his work, he had many other admirable qualities that played their part in making his life exceptionally useful.

Born in Liverpool 71 years ago, he came of a learned family, his father being a well-known classic and headmaster, whilst Joseph Hooker, the botanist, was his cousin. The young Dawson Turner was educated at Shrewsbury, and Dalhousie University, Nova Scotia, where he took an Arts degree in 1884. Returning to this country he went to Oxford and later to Edinburgh, graduating in medicine with honours in 1888. Appointment to the resident staff of the Royal Infirmary followed immediately and Turner became house physician to the late Sir James Affleck, thus beginning a lifelong friendship. In accordance with the custom prevailing at that time he proceeded to visit the principal continental medical schools—Paris and Vienna in particular. Even at this early stage his literary talent showed itself, and he published a short book on skin diseases. He was never much inclined, however, towards the practice of medicine except on its scientific side, and his thoughts began to turn towards physics in its relationship to medicine. It was not long before he started teaching medical physics at the Edinburgh Surgeons Hall, and on the publication of Rontgen's discovery he immediately secured an apparatus with a view to studying the importance of this new development as it affected medicine and surgery. With the plant which was installed at his home in George-square he made extensive experiments, and as precautions were then unknown he contracted a severe dermatitis of the right hand which was to cause him suffering for the rest of his life. A growing interest in the new science induced the managers of the Royal Infirmary to establish a medical electrical department, and in 1898 Turner was asked to join Dr. Milne Murray there as assistant, afterwards becoming his successor. Although now well aware of the danger attending it, he was in no way deterred from continuing experimental work, for with the discovery of radium by the Curies in Paris he immediately secured specimens and began work straight away, lending radium for the use of the Royal Infirmary electrical department until the managers secured a small supply of their own. "During the many years I was associated with him," writes one of his assistants at this time, "I gradually came to admire his originality of thought, his great gifts as a linguist, his facility of expression, and his ability to write papers on any aspect of medical electrotherapy. His 'Practical Manual of Medical Electricity' was for many years a standard work—indeed, up to the time of the war. His 'Radium: Its Physics and Therapeutics' was one of the first publications on this subject in the English language. His paper published in 1906 in the *Transactions* of the British Association on the Hæmorenal Salt Index and Efficiency of the Kidney was epoch-making, and by its means many of his colleagues were able to benefit their patients. It would occupy too much space to detail the papers known by me to have been published by my late chief; I never remember a year, unless laid aside by ill-health, when he did not write at least four."

DR. DAWSON TURNER
At the age of 40.

Turner always took great pains in the preparation of his experiments and demonstrations, alike for his classes—which were always well attended—and for the numerous scientific societies to which be belonged. In these preparations his wife was an interested and devoted assistant. His class in physics at the Surgeons Hall was always popular. He did everything he could to keep these lectures up to date and kept up the interest of his students in a way that few lecturers have the knack of doing. In this he was helped by an unusual personality. Six feet in height and of spare build, with the slight stoop of the student, he had a pleasing dignity and courtesy of manner. His face was grave almost to the point of sternness, but this impression was quickly dispelled by his genial smile. His moods were somewhat variable, and at times he was difficult to understand; but at heart he was one of the most kindly of men, having a gift for making and of keeping friends. The progress of his students in after-life was always a matter of great concern to him; their achievements gratified him and he kept in personal contact with a great number of them.

With an increasing disability from dermatitis it was not long before Dr. Turner's general health was undermined, and in 1911 he had to give up his principal duties as medical electrician at the Royal Infirmary. He was, however, able to take charge of the newly formed radium department, and he kept up his association with the institution over a period of some 30 years, during which he was a familiar figure in medical and scientific circles. It was painful to those who knew him well to see him gradually going downhill and more painful still to know that his sufferings were so long drawn out. Before he finally settled in Surrey two sojourns were made abroad, in Madeira and Switzerland, in the hope of improving his health. Neither, unfortunately, had any lasting benefit. "His enforced retirement from professional work and his severance from the Scottish capital were a great grief to him," writes another of his colleagues, "and in his letters he constantly asked for news of Edinburgh affairs and of his friends there. His fortitude through these long years of increasing disablement and suffering are an inspiration to many."

As an example of Turner's pioneer spirit it may be mentioned that he was the first motor owner and driver in Edinburgh. This pursuit originated in his interest for bicycling as a boy, when he was the owner of one of the high bone-shakers and even competed in cycling races. A love of sport in many forms remained throughout his life. At one time a very good billiard player, he had to abandon this pastime owing to increasing difficulty in holding the cue; but he went on playing golf until within two or three years of his death. From his house at Gullane in East Lothian he was able to enjoy the game on three courses—Gullane, Kilspindie, and Muirfield. His golf bag often excited curiosity and even amusement, for it contained only three clubs, but in spite of crippled fingers and failing eyesight he could still surprise opponents who expected an easy victory, for his accuracy was almost uncanny.

Dawson Turner was a good linguist and a keen musician, and was at one time President of the Royal Scottish Society of Arts. He was also an original member and a vice-president of the Rontgen Society.

He became M.R.C.P. Lond. and F.R.C.P. Edin. in 1890, and was also elected a Fellow of the Royal Society of Edinburgh. His wife, with whom he travelled over a great part of Europe, is the daughter of William Barry, of Romford. She coöperated in every part of his work, and at the same time had the sad satisfaction of attending to his wants during the long illness which it had brought about. For many years she shared with him in dispensing a delightful hospitality in Edinburgh and at Gullane.

CLARENCE LESLIE STARR, M.D. TORONTO.

WE much regret to learn of the death, which occurred on Christmas Day, of Dr. Clarence Leslie Starr, professor of surgery in the University of Toronto, and chief surgeon to the General Hospital in that city.

Clarence Leslie Starr was the son of Milton Starr, of Brooklin, Ontario, and was born in Georgetown, Ontario, in 1868. He was educated at the Whitby College Institute and the University of Toronto, where he graduated in medicine in 1890, and became house surgeon to the General Hospital. He then did much post-graduate work at Vienna and various centres in England, France, and Germany, and studied also for a period at the Bellevue Hospital Medical College, the medical school of New York University. While in New York he was interne at the Hospital for Ruptured and Crippled, and was also assistant surgeon in the out-patient department at the New York Hospital, becoming interested in this way in the subject of pædiatrics. Returning to Toronto he commenced practice there in 1896, and in 1897 joined the teaching staff of the medical faculty of the University as demonstrator of anatomy, a post which he held for four years until his election to the staff of the General Hospital and his promotion to be assistant professor of clinical surgery. The foundation of his well-known work in pædiatrics having been laid in New York, he pursued this branch of practice assiduously in the Hospital for Sick Children in Toronto, where he was appointed surgeon while serving on the staff of the General Hospital, and his various contributions to medical journals and to the American Practice of Surgery largely bear upon deformities of the spine. During the war he served, with the rank of lieut.-colonel, as consulting orthopædic surgeon to the C.A.M.C., and his early death is a real loss to that branch of surgery.

Prof. Starr married Annie Louise, daughter of the Hon. John Dryden, late Minister of Agriculture for the Province of Ontario, by whom he had four daughters.

WILLIAM WARWICK WAGSTAFFE, O.B.E., B.M. OXF., F.R.C.S. ENG.

WE have to record the death, on Dec. 27th, of Mr. W. W. Wagstaffe, surgeon to the Radcliffe Infirmary, Oxford, at the age of 42. His father, who bore the same name, was at one time senior assistant surgeon at St. Thomas's Hospital and the son inherited an anatomical and surgical bent. On leaving Charterhouse he went up to New College, Oxford, and was associated with Sir William Osler in a study of the works of the older anatomists, especially of Vesalius. He took a first class in the honour school of Natural Science in 1908 and then went to St. Thomas's Hospital, whence he qualified three years later. After holding the posts of house surgeon, casualty officer, and surgical registrar, he took charge of the British Red Cross Party sent to Greece during the Balkan War of 1913, and on coming back to England he became F.R.C.S. in 1914. Serving with the British Expeditionary Force throughout the late war he reached the rank of major in the Royal Army Medical Corps. He thus gained an immense surgical experience, especially of head injuries, in which he continued to be interested, as was shown by a recent contribution to our columns. For a short time after the war he acted as first assistant in the surgical unit at St. Thomas's Hospital under Sir Cuthbert Wallace. In 1921 he settled in Oxford as a surgeon and acted as demonstrator in the Department of Anatomy under Prof. Arthur Thomson. He was elected assistant surgeon to the Radcliffe Infirmary in 1924 and surgeon in 1927.

Dr. A. G. Gibson writes: "From the beginning of his work in Oxford we felt we had acquired a colleague who could bear responsibility in surgical work. From his continuous surgical experience following qualification he had attained to an easy familiarity with the main difficulties of surgical technique, and he was not given to adventurous surgery. These qualities made him admirably adapted to the surgical work of the Radcliffe Infirmary, which is very heavy, but which requires a conservative policy, for in the support that it receives from country districts heavy surgical risks without the clear possibility of good must be avoided. The writer is reminded of an incident in which Wagstaffe was unwilling to interfere in a case referred to him for operation. The woman had abdominal pain and vomiting which was thought to be due to slight obstruction, but without physical signs. It was characteristic of him that he allowed himself to be persuaded by his senior colleague which as the issue demonstrated was to the benefit of the patient. He regularly attended medical meetings both in Oxford and elsewhere, where he was a frequent contributor of papers and he spoke frequently in discussions. Neither personally nor professionally had he any showy qualities, but he did his surgical work easily and without fuss, and one could not be but impressed with the solid background of common sense which influenced all he did or said. He was simple in speech and very gentle in manner. I have never heard him say an unkind word, I have never seen him annoyed, and in situations in which other men might have made incisive comment he usually preserved a wholesome silence. We have lost one whose friendship was born of goodwill, a friendship that would have ripened as years went on."

Mr. Wagstaffe married in 1916 Margaret, daughter of Mrs. Cuthbertson, of Broughty Ferry, and there are two children of the marriage. His widow and mother will receive the sympathy of all who knew him.

WILLIAM THORNBOROUGH HAYWARD, C.M.G., M.R.C.S. ENG., LL.D.

WE regret to announce the death at Adelaide on Dec. 21st last of Colonel W. T. Hayward, hon. consulting physician to the Adelaide Hospital, and a much respected member of the medical profession in Australia. He was born at Reading on June 26th, 1854, educated at St. John's College, Hurstpierpoint, and the Liverpool School of Medicine. After qualifying L.R.C.P. Irel. and L.M. in 1874, and taking the M.R.C.S. Eng. in the following year, he held some resident hospital appointments before leaving for South Australia in 1878. Settling at Norwood, he soon became attached to the General Hospital at Adelaide, where he was on the full medical staff for a period of 30 years until 1914, when he resigned to join the Australian Imperial Force and was appointed a member of the governing body. He lectured on clinical medicine and materia medica at the University, serving also on the council. He became president of the Permanent Medical Referee Board of the A.A.M.C. (4th Military District) and was a vice-president of the British Medical Association at the time of its Aberdeen meeting in 1914, when he received honorary degrees from the Universities of Aberdeen and Adelaide in recognition of having devoted his great administrative abilities to organising the profession of medicine throughout the Commonwealth. He was 60 years of age at the outbreak of the war, and for three years, 1915–18, was in charge of the Australian Auxiliary Hospital at Harefield. For his services he was made C.M.G. in 1919. Colonel Hayward married Florence, daughter of the late P. H. Burden, of Adelaide, by whom he had one son.

Medical News.

UNIVERSITY OF OXFORD.—At recent examinations the following candidates were successful:—

B.M., B.CH.

Medicine, Surgery, and Obstetrics.—A. R. Bowtell, S. B. Davis, R. M. J. Harper, *G. G. Hill, R. G. Macbeth, D. C. Shields, *Margaret A. L. Herbertson, and *Joyce Wright.

Pathology.—G. H. Bateman, Fairfax Bell, J. F. Brock, J. L. Clapham, Arthur Guirdham, M. A. Hatt, J. C. Leedham-Green, W. H. McMenemey, *J. C. Neely, J. N. O'Reilly, R. S. B. Pearson, B. T. Squires, Anne D. M. Adams, Olive M. Capper-Johnson, Amy C. E. Clarke, and Victoria M. Robinson.

Forensic Medicine and Public Health.—H. R. J. Donald, J. A. Eddy, R. G. Macbeth, H. E. Mansell, *J. C. Neely, J. C. Nicholson, G. P. Roxburgh, W. J. Walter, H. G. Wells, and Ruth Sandeman.

Materia Medica.—P. M. F. Bishop, J. F. Brock, J. M. L. Burtenshaw, E. C. Coaker, W. J. Cotton, R. F. Lomax, and R. L. H. Townsend.

* Received their degrees on Dec. 17th.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates were successful:—

Surgery.—E. A. Johnstone, Manchester and Charing Cross Hosp.; E. A. Lipkin, Liverpool and Charing Cross Hosp.; D. M. Nightingale, King's Coll. Hosp.; A. K. Rama Chandra, Edinburgh; and R. W. Scanlon, St. Thomas's Hosp.

Medicine.—W. S. Ghai, Charing Cross Hosp.; D. H. Haler, King's Coll. Hosp.; K. R. Lundeberg, Minnesota, U.S.A.; K. G. Milad, St. Mary's Hosp.; T. A. P. Proctor, Birmingham; A. K. Rama Chandra, Edinburgh; and H. Tenenbaum, Nancy and London Hosp.

Forensic Medicine.—W. S. Ghai, Charing Cross Hosp.; D. H. Haler, King's Coll. Hosp.; C. K. McCoan, St. Mary's Hosp.; J. H. McGibbon, Glasgow; K. G. Milad, St. Mary's Hosp.; and T. M. White, Bristol.

Midwifery.—W. D. Glynn-Jones, Guy's Hosp.; D. H. Haler, King's Coll. Hosp.; K. G. Milad, St. Mary's Hosp.; B. J. Niall, London Hosp.; K. M. Seedat, Charing Cross Hosp.; and T. M. White, Bristol.

The Diploma of the Society was granted to the following entitling them to practise medicine, surgery, and midwifery: W. S. Ghai, E. A. Lipkin, K. G. Milad, E. A. Johnstone, K. R. Lundeberg, T. A. P. Proctor, W. D. Glynn-Jones, A. K. Rama Chandra, and H. Tenenbaum.

THE death is announced of Sir George McCrae, Chairman of the Scottish Board of Health from 1919 to 1922.

EAST LONDON HOSPITAL FOR CHILDREN.—A clinical afternoon will be held at this hospital, Glamis-road, Shadwell, E., on Wednesday, Jan. 9th, at 4 P.M., when the subject of discussion will be Diseases of the Alimentary System. Medical practitioners are invited (tea 3.45 P.M.).

NATIONAL ASSOCIATION FOR PREVENTION OF INFANT MORTALITY.—A course of lectures on the Early Detection and Prevention of Defects and Disease in Young Children, intended mainly for health visitors, nurses, midwives, and superintendents of infant welfare centres, will be given in the Lecture Hall of the Infants Hospital, Vincent-square, Westminster, S.W., on Mondays, from 6.30 to 7.30 P.M., from Jan. 7th to March 11th. The lecturers will be Dr. F. J. Poynton, Dr. Eric Pritchard, Dr. W. E. Robinson, Dr. A. G. Maitland-Jones, Dr. C. Worster-Drought, Mr. Alan Todd, Dr. Donald Paterson, Dr. Letitia Fairfield, Dr. R. C. Wingfield, and Mr. H. R. Jeremy, Tickets may be had from the hon. secretary of the Association at 117, Piccadilly, London, W.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—At 8.30 P.M. on Friday, Jan. 11th, at the West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, London, Mr. Lindsay Rea will give a demonstration on the Fundus Oculi. This demonstration is limited to 12 persons and is especially designed for candidates for the M.R.C.P. examination. Application for attendance should be made to the Fellowship (Tel.: Mayfair 2236). From Jan. 14th to 25th an intensive course will be held at the National Hospital for Diseases of the Heart. The entry is limited to 20 and early application is therefore desirable. An all-day course will be given at the Queen's Hospital for Children from the 14th to the 26th, and the staff of the Prince of Wales's General Hospital will hold an intensive course in medicine, surgery, and the specialties, primarily intended for practitioners, from Jan. 28th to Feb. 9th (daily from 10.30 A.M. to 5.30 P.M.). A series of lecture-demonstrations in Psychological Medicine will be given on Tuesdays and Saturdays at 11 A.M., from Jan. 29th to Feb. 23rd, at the Bethlem Royal Hospital. Copies of all syllabuses, together with information about the General Course arranged by the Fellowship, may be had from the Secretary at 1, Wimpole-street, London, W.

Mr. Robert Ollerenshaw, clinical lecturer in orthopædic surgery in the University of Manchester and orthopædic surgeon to the Royal Manchester Children's Hospital, has been elected a member of the French Orthopædic Association.

DEVONSHIRE HOSPITAL, BUXTON.—This hospital has received a bequest of £5000 from the trustees of the late Mrs. Ada Mary Cryer, of Rochdale, for the endowment of five beds to be known as the Cryer beds, for the free use of patients of the county borough of Rochdale.

GREENOCK EYE INFIRMARY.—More than 5400 patients were treated at this hospital during the year, 4100 of whom were males. There were 2400 cases of the removal of minute pieces of metal and other substances.

S. R. WILSON MEMORIAL PRIZE.—It is announced by the editor of the *British Journal of Anæsthesia* that the prize of £50 given in memory of Dr. S. R. Wilson for research on inhalational anæsthesia has been awarded to Dr. Florence Violet Stephen, M.Sc., who is at present working at the Manchester Royal Infirmary.

POST-GRADUATE LECTURES AT ROYAL NORTHERN HOSPITAL.—A series of lectures and demonstrations will be held at this hospital on certain Tuesday afternoons from January to April, and will be succeeded by three lectures at the Royal Chest Hospital on Wednesdays in May. A fortnight's special course in gastro-enterology will begin on Jan. 28th, and from Feb. 18th to 22nd an "intensive week" of post-graduate lectures has been arranged, including teaching in wards and other departments during the morning. Notices of the weekly lectures will be found in our Medical Diary, whilst particulars of the special courses and of other post-graduate work may be had from the Dean of the Hospital, Holloway-road, London, N.

Appointments.

DATE, W. ADLINGTON, M.B., B.S. Lond., L.R.C.P. Lond., M.R.C.S., has been appointed Honorary Assistant Anæsthetist to the Royal Devon and Exeter Hospital.

GILMORE, E. R. W., M.B., Ch.B. Manch., D.P.H., D.T.M., Medical Officer of Health at Port Louis, Mauritius.

HEALY, T. M., M.B., B.Ch. N.U.I., Master of the Coombe Hospital, Dublin.

MAQUIRE, T. J. R., M.B., B.Ch. N.U.I., D.P.H., Assistant Medical Officer of Health, Cork.

London Jewish Hospital, Stepney Green, E.: KRESTIN, D., M.D., M.R.C.P. Lond., Honorary Assistant Physician; and MANDEL, L., M.D., M.R.C.P. Lond., Honorary Physician (promoted).

Consideration is being given to the appointment of an additional Ophthalmic Specialist Medical Referee under the Workmen's Compensation Act for the following county courts in Circuit No. 31: Aberayron, Aberystwyth, Cardigan, Carmarthen, Lampeter, Llandilo Fawr and Ammanford, Llandovery, Llanelly, Narbeth and Haverfordwest, Neath and Port Talbot, Newcastle-in-Emlyn, and Pembroke Dock. Applications should reach the Private Secretary, Home Office, Whitehall, London, not later than Jan. 19th.

Vacancies.

For further information refer to the advertisement columns.

Barbados General Hospital.—Jun. Res. S. £250.

Brighton, Royal Sussex County Hospital.—Jun. Asst. Pathologist. £250.

British Pharmacopœia Commission, 44, Hallam-street, W.—Secretary. £500.

Buxton, Devonshire Hospital.—Asst. H.P. At rate of £150.

Central London, Throat, Nose and Ear Hospital.—Two Hon. Asst. Out-patient Registrars.

Chester, Royal Infirmary.—Third Hon. Surgeon.

Doncaster Royal Infirmary.—Second H.S. £150.

Great Yarmouth, General Hospital.—H.S. £150.

Guildford, Royal Surrey County Hospital.—Hon. Asst. Surg.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. £50.

Hospital for Sick Children, Great Ormond-street, W.C.—Res. Med. Supt. £300. Also Anæsthetist. 15 gns.

Hove, Lady Chichester Hospital.—H.P. Also Jun. H.P. At rate of £100 and £50 respectively.

Ilford Emergency Hospital, Ilford, Essex.—Jun. H.S. £100.

Inverness, Northern Infirmary.—H.P. and Jun. H.S. £100.

Lahore, Dental Hospital.—Dental Surgeon. Also Dental Mechanic. Rs.1000–50—1500 and Rs.400–20—800 per mensem respectively.

Leamington, Warwickshire and Coventry Joint Committee for Tuberculosis.—Asst. Tuber. O. £650.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Liverpool, Mill-road Infirmary, Everton.—Res. Asst. M.O. £200.

Llangwyfan, near Denbigh, North Wales Sanatorium.—Third Asst. Res. M.O. £250.

L.C.C., Mental Hospital Service.—Eighth Asst. M.O. £300.
L.C.C.—Temporary Asst. M.O.'s. 30s. per session.
London Female Lock Hospital, 283, Harrow-road, W.—H.S. £150.
London Temperance Hospital, Hampstead-road, N.W.—Med. Reg. 40 guineas.
Lowestoft, S. Luke's Hospital.—Jun. Asst. M.O. £500.
Manchester, Ancoats Hospital.—Res. M.O. £150.
Manchester Royal Infirmary.—Four H.P.'s. Each at rate of £50. H.S. to Aural, Gynæcological, and Ophthalmic Dept. At rate of £50. Also Five H.S.'s. Each at rate of £50.
Manchester, St. Mary's Hospitals.—Four H.S.'s. Each at rate of £50.
Marseilles, Queen Alexandra Memorial Hospital.—Res. M.O. At rate of £150.
Metropolitan Asylums Board Mental Hospital Service.—Jun. Asst. M.O. £500.
Nottingham, Bagthorpe Institution and Infirmary.—Res. Asst. M.O. At rate of £300.
Oswestry, Shropshire Orthopædic Hospital, &c.—H.S. £200.
Paddington Green Children's Hospital, W.—Two Hon. Surgeons.
Port Said, British Hospital.—Res. Asst. M.O. £350.
Preston and County of Lancaster, Queen Victoria Royal Infirmary. H.P. £190.
Rochdale Infirmary and Dispensary.—Jun. H.S. £175.
Royal Army Medical Corps.—Twenty-five Commissions.
Royal Northern Hospital, Holloway, N.—Obstetric Physician.
St. John's Hospital, Lewisham, S.E.—Res. Cas. O. Also Jun. House Officer. Each at rate of £100.
St. Paul's Hospital for Diseases of the Genito-Urinary Organs and Skin, Ednell-street, W.C.—H.S. At rate of £150.
St. Thomas's Hospital.—Obst. P. Also Obst. P. in Charge of Out-patients.
Stoke-on-Trent, North Staffordshire Royal Infirmary, Hartshill.—Hon. Asst. Physician.
Staffordshire Mental Hospital, Cheddleton, Leek.—Second Asst. M.O. £650.
Sudan Medical Service.—M.O. LE.780.
Swansea County Borough.—Asst. M.O. £600.
University College Hospital, Gower-street, W.C.—Hon. Clin. Asst. to Ophth. Out-patient Dept.
Victoria Hospital for Children, Tite-street, Chelsea, S.W.—H.P. Also H.S. Each at rate of £100.
West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Sen. H.P. Also Jun. H.P. At rate of £150 and £100 respectively.
West London Hospital, Hammersmith-road, W.—Aural and Ophth. H.S. and Res. Asst. Cas. O. At rate of £100.
Westminster Hospital, Broad Sanctuary, S.W.—House Anæsth. At rate of £50.
Whipps Cross Hospital, Whipps Cross-road, Leytonstone, E.—Anæsthetist. £200. Also Specialist Consultants. Special Fees.
Willesden General Hospital.—Clinical Assistants.
Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Lockersbie (Ayrshire) and Llansawel (Carmarthenshire).

Births, Marriages, and Deaths.

BIRTHS.

CORSI.—On Dec. 29th, 1928, the wife of Henry Corsi, F.R.C.S., Harley-street, W., of a son.
MACKAY.—On Dec. 29th, 1928, at Blackheath, the wife of S. Ruthven Mackay, R.A.M.C., of a son.
PYPER.—On Dec. 18th, 1928, at The Old Ford House, Blandford St. Mary, the wife of Major J. C. Pyper, I.M.S., of a daughter.
WIGHT.—On Dec. 27th, 1928, the wife of Cecil H. Wight, *M.C.*, M.R.C.S., L.R.C.P., of Wangford, Lowestoft, of a daughter.
WORSELDINE.—On Dec. 21st, 1928, in London, the wife of Stanley C. H. Worseldine, Captain, I.M.S., of a daughter.

MARRIAGES.

CROFT—LEE.—On Dec. 29th, 1928, at All Saints' Church, Compton, Winchester, Charles Richard Croft, B.A., M.R.C.S., L.R.C.P., to Phyllis Mary, only daughter of Mr. and Mrs. A. C. Lee, of Hatch Thoke, Compton.
GILMORE—FORSYTH.—On Dec. 22nd, at St. Cuthbert's, Withington, E. R. W. Gilmore, M.B., Ch.B., D.P.H. Vict., D.P.H. Lond., D.T.M. Liverp., second son of Mrs. Gilmore, of Fallowfield, Manchester, and the late R. O. Gilmore, LL.B., to Ella, only daughter of Mr. and Mrs. Hy. Forsyth, of Athol-road, Manchester, and of Northsyde, Berwick-on-Tweed.
RUTHERFORD—FLECK.—On Dec. 28th, 1928, at Wilton Parish Church, Hawick, N.B., Andrew Rutherford, M.B., F.R.C.P. Edin., to Mary Rose, widow of James Fleck, C.A.

DEATHS.

HOLMES.—On Dec. 24th, 1928, at Foxhall-road, Nottingham, Dr. T. E. Holmes, M.A., M.D. Camb. and Lond., County Medical Officer for Nottinghamshire.
MAKALUA.—On Dec. 31st, 1928, at Warrior-square, St. Leonards-on-Sea, Matthew M. Makalua, M.R.C.S., L.R.C.P.
STARR.—On Christmas Day, at Toronto, Dr. Clarence Leslie Starr, Professor of Surgery at the University of Toronto.
TURNER.—On Christmas Day, 1928, after long suffering from his pioneer X ray work, Dawson Fyers Duckworth Turner, M.D.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE FRENCH MEDICAL SERVICES IN THE WAR.

GENERAL MIGNON'S STORY.

Inspector-General A. Mignon, D.M.S. of the Third Army, was stationed in the Verdun area from the commencement of the war to November, 1918, when he was retired just before the Armistice on account of age. A practised author, with several books to his credit, he had been the Director of the Army Medical School at Val-de-Grâce when war broke out, and has lately been given facilities for reading original documents. He is thus well qualified to give an account of the development and service of the French medical corps throughout the war.[1] His work is arranged in four well-printed volumes, the first describing the period of education, the second, Verdun, the third, 1917 and 1918, while the fourth embodies reflections and deductions from a survey of the whole period. Military surgeons must in times of peace imagine what they will have to do in war. In the past manœuvres instructed only junior officers, the schemes of seniors were not criticised, and the staff appeared to think that removal of wounded from the battlefield was all that was required from the medical service. In the war the lack of coöperation between the medical and the General Staff was at first a serious impediment. Administrative difficulties were great: if small-pox broke out, 20 telegrams must be sent before one man was vaccinated. Antityphoid inoculation had been ordered to begin in October, 1914 (the vaccine, an autolysate, gave more reaction than the English), and General Mignon could not get any when he applied for it in August, 1914. The generals all wanted the wounded made comfortable, but administration was with the Chief of Staff; the Staff moved the medical units and the D.M.S. could neither detail his staff, nor get news of any intended operations. At first all wounded were sent down: blankets, food, medical instruments were lacking. In 1914 a mobile operating room, sent up by the Duchesse d'Uzès and Prince Platoff, did splendid work but was unapproved, and it was not until 1915, when the surgeons of Paris sent up another, that these mobile units became generalised. At first the trains for wounded were ill-equipped, slow, and gave no food, and there was but one section of motor ambulances. When the author had many casualties and few hospital beds, he asked to be given barracks, and got them, it being less hurtful to a sound man than to a sick one to sleep in a tent. The needs of the medical service had not been visualised; no one had stood up for the medical officer, or rather for the wounded and sick whom he protects. In treating wounds at first too much iodine was used, then came ether, and Abadie, of Oran, got striking success with 7 per cent. NaCl, but all antiseptics tried gave poor results. Then came Dakin's solution, and with the excision of wounds, Carrel-Dakin's method worked wonders. As to hygiene, in October, 1914, typhoid (335 cases) was recognised at Verdun. In 17 months the Third Army had 39,712 cases with 3384 deaths; the numbers for the same period in the B.E.F. are quoted as 2796 with 178 deaths (p. 535). The French soldier is not a drinker of hot water, like the Englishman, but chlorination of water stopped typhoid. Company officers took the greatest trouble in looking after their men, getting them dining-rooms to keep flies out of sleeping places, finding better clothes for them and steel hats; baths were set up in 1915, a laundry in 1916.

Verdun.

Mignon, when D.M.S. of the Third Army, was on Feb. 1st, 1916, put in medical charge of the adjacent but distinct Fortress of Verdun. On Feb. 9th he received information that the Germans would attack on the 15th. The hospitals were cleared in 48 hours, medical and venereal cases sent away, and stores were obtained. Mignon planned to link forward and rear units so as to get quick evacuation for wounded, and tried to collect surgical units. The Third Army sent him orderlies, stretcher-bearers came from Paris, and with their help a hospital of 350 beds was built at Baleycourt, and others were rearranged, restaffed, re-equipped. On Feb. 15th came a fierce storm of snow and bitter cold, so some extra time was gained; but it cleared suddenly on Feb. 20th, and on the next day the shelling began. Aid posts, field ambulances were swept away. One division lost 21 doctors; hospitals came under fire, and Baleycourt had to close on Feb. 28th. Throughout the next four months the routes of evacuation and the positions of hospitals were

[1] Le Service de Santé pendant la Guerre, 1914–18. By Médecin Inspecteur-Général A. Mignon. Paris: Masson et Cie. In four volumes. Vol. I., pp. 697, 1926; Vol. II., pp. 690, 1926; Vol. III., pp. 703, 1926; Vol. IV., pp. 831, 1927. Fr.240.

constantly changing. The first thing to provide in a new place was a surgical unit, with beds around it, then an examining post outside the hospital to feed and dress walking wounded, sent on by returning supply lorries. Later hospital huts were put closer together to save fatigue to the staff. Connecting wooden paths proved dangerous, for they burned one hospital in an air raid. General Mignon emphasises the importance of having subsidiary hospitals into which to relieve evacuation hospitals when these are likely to be submerged in a sudden flood of casualties.

The Somme and After.

The third volume deals with the Somme in 1916, the battles of 1917, the German attacks of 1918, and the victorious advance of 96 days before the Armistice. Preparing for the Somme, medical officers were directed to keep the walking wounded in the army areas, to take out of the areas the seriously damaged, and to make comfortable arrangements for the others. Large hospitals were placed 10 miles behind the lines, but they had not enough surgeons, so Amiens had to take the overflow. Before the battle of the Aisne (April, 1917) Parliament had disestablished the Director-General of the Armies, who was in fact replaced by a captain of the General Staff. General Nivelle had no medical officer on his staff either, and the new M.O.'s of the armies concerned were not told the idea nor the zero. The hospital scheme, devised in Paris, was too ambitious and not completed in time. Weather turned against the force, and the senior medical officer of the flank army had hastily to hospitalise 2652 lighter cases in a village. The attack failed, and the medical units were swamped. One of 1300 beds had 6000 cases to deal with. Visiting members of Parliament were shocked, and the medical service was blamed, but as our author, with scientific detachment, observes, the War Office should take the blame for the failure of its own scheme, or alternatively the General who underestimated his probable losses and engaged before the medical arrangements were completed. Later the medical officers got better information and their organisation was improved. In the 1917 offensives in Flanders the plans of the Paris Society of Surgeons were accepted; walking wounded were early separated, the best surgeons of Paris, at the front, cleaned the wounds at once, and patients were sent to the rear for suture, with excellent results, partly because only half the expected wounded appeared. In the German offensive of March, 1918, when the front was bent, chaos reigned. It is little use sending up a division in relief without its medical units, and these can do nothing without equipment. The month before July, 1918, when the 96 days of final advance began, the armies had been told to prepare to advance, and hospitals to divest themselves of extra stores. Gas was now a great trouble; the faster the Germans retired the more gas they sent over. A service for gassed men was set up parallel to that for wounded. In October cold became a difficulty, but especially influenza (36,304 cases that month); other diseases seemed to hold up in its presence. Barges made good means of evacuation. The hospitals of evacuation had by now many special divisions, eyes, face, and so forth. Divisional and forward units only prepared cases for evacuation; surgery was done by corps units or behind. This proved to be the best system.

Reflections and Deductions.

In his fourth volume, of reflections and deductions, Inspector-General Mignon expresses the view that the great cause of the success of the medical service in the war was the assimilation of the civil medical profession into the army. Military medical officers remained in touch with the command, and provided for the civil profession the means for doing their work, which was the care of the sick and wounded. Surgery was no longer thought a general service duty, but was restricted to specialists, and similarly other branches of medicine. The military medical service had itself undergone evolution. At the close there was a medical officer on the staff of every general; the medical officers knew how many casualties to expect, and when and where; they moved their units and sent the sick to whatever place they considered most conducive to a speedy recovery. They have not even yet got full command in their hospitals, nor the complete autonomy of a corps. Originally governed by a director on the "7th Direction" of the General Staff, after a year of war the "Service de Santé" was put under an Under Secretary for War. An Under Secretary of State is less hampered than a soldier by precedent, or by finance, and he has a numerous staff to help him; through his agency came consulting surgeons and physicians, inter-Allied surgical conferences, increased autonomy, and more reasonable relations with the command. When he relieved Nivelle Pétain felt that the Service de Santé was insufficiently represented at Headquarters, and added an inspector there to advise on coördination. Thus, thanks to many motor vehicles and to better relations with the railways, the war ended more comfortably for the wounded than it began; at least 80 per cent. of them were made fit to return to the line. The author's final conclusion as to the best method of procedure appears to be that divisional and forward units should collect the wounded, do first-aid, fill up the field cards correctly if possible, and deliver the patients to Corps, at the head of the car line, where the consulting surgeon will examine them, send the walking wounded in lorries some 100 miles back, retain untransportable cases (on whom he himself may operate, if he has time), and send the others to the hospitals of evacuation, special or general, 12 or more miles to the rear. Thus will the front be cleared to the best advantage, and thus also will the patients recover best. Inspector-General Mignon hopes there will never be another war, but fears that as usual, people will forget the horrors, and that increasingly as time goes on, only the self-sacrifice and nobility of the soldiers will be recalled. Therefore it is essential to remember the steps which eventually led to the building up of a fine Service de Santé.

THYROID METABOLISM, IODINE, AND VITAMINS.

THE remarkable effect of iodine in exophthalmic goitre is now well known, though it is not yet understood how it is brought about. In almost every case iodine causes an immediate slowing of the pulse-rate, lessening of the nervous symptoms and exophthalmos, and a fall of basal metabolic rate (B.M.R.) often to normal. These effects are not permanent, and usually there is a relapse after a few weeks, even though iodine is continued. The relationship of hyperthyroidism induced by thyroid feeding to exophthalmic goitre is not clear, but it is recognised that the latter is a more complicated condition than can be induced by mere excess of thyroxin. In this connexion the observations of D. A. Carson and William Dock [1] on the action of iodine on hyperthyroidism produced in man by thyroid feeding are of interest. They point out that the evidence on this subject from animal experiments is contradictory and they have been fortunate in being able to observe the effect of iodine on artificial hyperthyroidism in four male patients. Hyperthyroidism of the type commonly seen in human beings was first caused by thyroid feeding in four adult males, an increased basal metabolic rate of between 20 and 30 per cent. being obtained in each case. Lugol's iodine was then given and the effect on the clinical condition and B.M.R. was observed. In Case 1 the giving of iodine coincided with a reduction in dosage of thyroid, so the experiment was vitiated; in Case 2 iodine was given for three days only, but no effect could be observed; in Cases 3 and 4 six days' iodine therapy had no effect whatever on clinical signs or B.M.R. Carson and Dock think that this negative effect in patients with a healthy thyroid gland suggests that in pathological hyperthyroidism the gland itself is the site of the action of iodine. They also regard these results as further evidence against the theory of a qualitatively perverted secretion. It might, however, be argued that they are in accord with Plummer's theory that the symptoms of exophthalmic goitre are due in part to the secretion by the thyroid gland of an iodine-deficient catalyst and are therefore partially relieved by iodine, whereas those of simple over-secretion of the gland are not affected by iodine.

The relation of vitamins to iodine metabolism is another aspect of the subject that has been under consideration. D. Harvey,[2] of the Rowett Research Institute, has observed that if cod-liver oil (which contains iodine) is given to goats it causes more iodine to pass into the milk than is obtained when the goat is fed on equivalent amounts of potassium iodide and olive oil. From this it was deduced that some effect on iodine metabolism might be got from specific constituents of cod-liver oil, and good results have been reported in cases of Graves's disease with a preparation (vitiodum) which consists of iodised jecoleic acid incorporated with a vitamin concentrate from the oil. Some results of this treatment are reported by G. L. Adamson and A. T. Cameron,[3] of the University of Manitoba. These observers studied the effect of the combination in 12 cases of exophthalmic goitre, and found that it is as effective as Lugol's solution, and that its effects are equally limited. The same initial fall of basal metabolism was observed as with Lugol's solution, and this was accompanied by the same fall in pulse-rate and clinical improvement. With continued treatment there was usually a slight relapse, and withdrawal was followed by a rapid rise in the patient's B.M.R. and pulse-rate. For some cases the vitiodum was divided into two parts, one containing the iodised fatty acid only and the other the vitamins A and D only. In four cases these were given separately at first and later in combination. Two of these showed no definite lowering of the B.M.R. when the vitamin fraction was given alone, but one of these afterwards responded

[1] Amer. Jour. Med. Sci., 1928, clxxvi., 701.
[2] Biochem. Jour., 1927, xxi., 1268.
[3] Canad. Med. Ass. Jour., 1928, xix., 420.

satisfactorily to Lugol's solution, and the second to vitiodum. Two others which failed to respond to the iodised fatty acid fraction both gave a characteristic remission with vitiodum, While admitting that the number of cases is insufficient for definite conclusions, the authors suggest that the combination of iodised fatty acid and vitamins is necessary for a definite effect. Whether one or both vitamins are necessary, and whether the iodised fatty acid can be satisfactorily replaced by other iodine compounds has yet to be proved. They think that this may be an example of positive vitamin action which should be carefully studied because it is in contrast to their negative action in deficiency diseases. They apparently do not consider the small amount of iodine present in vitiodum enough by itself to produce the effect of the much larger amount of iodine in Lugol's solution. It is strongly emphasised that further work is necessary both to confirm the results and to investigate the possible relationship between vitamins A and D, the thyroid and iodine metabolism.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Jan. 8th.—5 P.M., THERAPEUTICS. An informal discussion on the Treatment of Established Diabetic Coma. The following have been invited to take part: Dr. E. P. Poulton, Dr. George Graham, Dr. R. D. Lawrence, Prof. MacLean, Dr. Otto Leyton, Prof. H. H. Dale, and Dr. P. J. Cammidge. 8.30 P.M., PSYCHIATRY. Discussion: Light Therapy in Mental Hospitals. Speakers: Dr. H. Dove Cormac, Dr. A. C. Hancock, Dr. G. de M. Rudolf, Sir Henry Gauvain, and Dr. R. Bourdillon. ELECTRO-THERAPEUTICS. Members of this section are cordially invited to attend the discussion.

THURSDAY.—5 P.M., BALNEOLOGY. Papers: Dr. David Brown and Dr. Woodmansey: The Excretion of the Constituent Ions of Sulphur Water in Fæces, Urine, and Sweat. Mr. Joseph Race: The Sedimentation Test. THERAPEUTICS AND PHARMACOLOGY. Members of this section are cordially invited to attend the meeting of Section of Balneology. 8 P.M., NEUROLOGY. Clinical meeting at National Hospital, Queen-square.

FRIDAY.—5.30 P.M., CLINICAL. (Cases at 5 P.M.) 8.30 P.M., OPHTHALMOLOGY. (Cases at 8 P.M.) Papers: Mr. M. L. Hepburn: An Attempt to Classify (Pathologically) the Various Fundus Pictures in Diseases of the Choroid. Mr. M. S. Mayou: Juvenile Glaucoma.

SOCIETY FOR THE STUDY OF INEBRIETY.

TUESDAY, Jan. 8th.—4 P.M. (in the Rooms of the Medical Society of London, 11, Chandos-street, W.), Miss C. Chisholm, M.D.: Alcohol and Drug Addiction in Rélation to Women and Children. Discussion.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 7th, to SATURDAY, Jan. 12th.—WEST END HOSPITAL FOR NERVOUS DISEASES, Gloucester Gate, Regent's Park, N.W. Fri., at 8.30 P.M., demonstration on the Fundus Oculi by Mr. Lindsay Rea. Ophthalmoscopes required. Especially suitable for M.R.C.P. candidates. Further particulars from Secretary, Mayfair 2236.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Jan. 7th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 8th.—3.15 P.M., Mr. L. E. Barrington-Ward: Modern Methods in Treatment of Malignant Diseases.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Jan. 7th.—1.30 P.M.: Methods of Examination and Diagnosis Courses—Hearing Tests.

WEDNESDAY.—1.30 P.M.: The Sinuses.

FRIDAY.—4 P.M., Mr. H. Kisch: Nasal Obstruction.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

THURSDAY, Jan. 10th.—5 P.M., Dr. W. N. Goldsmith: General Eruptions in Children.

ROYAL SANITARY INSTITUTE, 90, Buckingham Palace-road, S.W.

TUESDAY, Jan. 8th.—5.30 P.M., Prof. A. Bostock Hill: Cleanliness: Is it the Basis of Health? Discussion.

LEEDS MEDICAL SCHOOL.

WEDNESDAY, Jan. 9th.—3.30 P.M., Prof. W. Blair Bell: Lead in the Treatment of Cancer.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURE, Manchester.

FRIDAY, Jan. 11th.—4.30 P.M. (at the Whitworth-street West Branch), Dr. Fletcher Shaw: Delayed Labour.

THE KING'S ILLNESS.

OFFICIAL BULLETINS.

(*Continued from p. 1372.*)

THE following is the text of the official bulletins which have been issued during the past week and signed by Sir Stanley Hewett, Sir Hugh Rigby, and Lord Dawson of Penn:—

THURSDAY, DEC. 27TH, 1928. 8.20 P.M.

During to-day His Majesty's condition has not been so satisfactory. There has been disinclination to take nourishment, and the strength has been less well maintained.

FRIDAY, DEC. 28TH. 11.45 A.M.

The King had a fair night with quieter sleep towards morning. There is less difficulty with the taking of nourishment, and the general state has improved during the last 12 hours. At a consultation this morning the progress of the past week was reviewed. During that period there has been a definite improvement in the local condition. On the other hand, the general condition, as evidenced by weight and strength, does not show the same progress. Measures best adapted for meeting this difficulty were considered and determined. (Signed also by Sir Farquhar Buzzard and Sir Humphry Rolleston.)

8.15 P.M. The King has had a restful day. The slight improvement noted this morning is maintained.

SATURDAY, DEC. 29TH. 11.30 A.M.

The King has had a quiet night, and there is a very slight change for the better in His Majesty's condition.

8.15 P.M. The King has had a quiet day. The slow improvement noted this morning continues. No bulletin will be issued till to-morrow evening.

SUNDAY, DEC. 30TH. 8.30 P.M.

The King has had a quiet day. There is no change to report in His Majesty's condition.

MONDAY, DEC. 31ST. 11.55 A.M.

The King has passed a somewhat restless night. The general condition is maintained, although as previously noted the state of exhaustion still presents a difficult problem. There is a little more readiness to take nourishment, and the local condition is progressing. (Signed also by Sir Farquhar Buzzard and Sir Humphry Rolleston.)

8.30 P.M. The King has had a good day. There is no change in the conditions noted this morning. Bacteriological examination shows that the extent and potency of the local infection are diminishing. (Signed also by Dr. L. E. H. Whitby.)

TUESDAY, JAN. 1ST, 1929. 11.15 A.M.

The King has had a good night. The general and local conditions are unchanged.

8.15 P.M. The King has had a restful day and there is a slight improvement in the general condition. Administration of calcium, based on chemical examination of the blood, is producing beneficial results. (Signed also by Prof. Edward Charles Dodds.)

WEDNESDAY, JAN. 2ND. 11.15 A.M.

In spite of a restless night the condition of His Majesty remains unchanged from last evening.

8.15 P.M. The King has passed a good day and there is a slight improvement in his condition

INDEX TO "THE LANCET," VOL. II., 1928.

THE Index and Title-page to Vol. II., 1928, which was completed with the issue of Dec. 29th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

An Address

[ABRIDGED]

ON

PITFALLS IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS.

Delivered before the North-Western Tuberculosis Society

BY S. VERE PEARSON, M.D. CAMB., M.R.C.P. LOND.,

PHYSICIAN TO THE MUNDESLEY SANATORIUM.

A PITFALL is a trap to catch the unwary. To be wary is to be on the qui vive for dangers. A diagnosis is the recognition in the patient of a known disease from the symptoms which are characteristic of it. When pulmonary tuberculosis is to be defined it is necessary to recognise that, like many another disease, the condition is a process rather than a state, and that the treatment, as of all other diseased conditions, is the treatment of a patient and not of a disease. It is difficult always to realise this in these days of notification, when a patient has to be labelled with a disease by decree from a Government department. Pulmonary tuberculosis may be present yet it may be old and inactive. The important point to recognise is that the presence of the disease must be producing ill-health and must be diagnosed from the history and symptoms. As Dr. F. G. Chandler has said, "If the profession is going to continue to place reliance on physical signs and X rays as a means of diagnosis, countless tragedies will continue to happen."

The commonest symptoms indicating active pulmonary tuberculosis are cough, fever, pain, and lassitude. Dr. I. Struthers Stewart,[1] after examining 200 consecutive admissions to his sanatorium, set out the percentage occurrence of these symptoms as follows: cough 60, lassitude 48, pyrexia 42, hæmoptysis 27·8, loss of weight 12. But he omitted to note pain, which I have found in 70 per cent. It should, therefore, receive greater attention, and is often helpful in arriving at a diagnosis.

For example, a young married woman who was admitted to Mundesley Sanatorium a year or two ago had had repeated pains about the upper part of her left chest which had been labelled muscular rheumatism. The loss of weight she had experienced was ascribed to the vomiting of pregnancy and to mental worry. Many months after her confinement, because of a slight cough with a little expectoration, her chest was examined and X rayed, and this revealed fresh excavations at both apices.

E. E. Prest, investigating the history of hæmoptysis, pointed out some years ago that there was usually three years' delay between the initial hæmorrhage and the admittance to a special institution. If doctors were more regularly trained to ask for a specimen of sputum and to have it examined for *Bacillus tuberculosis* whenever suspicion of pulmonary tuberculosis was present, there would be fewer unwary ones and fewer unfortunates caught in a trap. Students and practitioners do not get sufficiently ample opportunities of seeing tuberculous cases which are relegated to the special dispensary and public institutions in the country. In Manchester, however, as also in Edinburgh and in one or two other places in England—though they are the exception—a tuberculosis expert who is also a servant under the public tuberculosis services is engaged to teach students. Manchester also has the advantage of an expert radiologist, well versed in chest work, as a teacher at the University.

If sputum is persistently negative for tubercle bacilli, especially if it is profuse, and the fingers are clubbed, bronchiectasis must be thought of. An intratracheal injection of lipiodol will clear up the diagnosis.

[1] See THE LANCET, 1925, i., 927.

Once in the last 25 years I have known a case of bronchiectasis in which tubercle bacilli were reported to have been found in the sputum on one occasion. Yet never, over the course of many years, did they recur, nor at any time did any signs or symptoms of tuberculosis appear in this patient. The slight unilateral bronchiectasis was rather difficult to demonstrate because it was on the left side and apt to be masked by the heart shadow. Yet when I established the correct diagnosis it made a great difference to the patient, a young man whose career was being damned by the label of pulmonary tuberculosis. His only symptom had been hæmoptysis; yet he had been condemned to a very restricted and guarded existence. He has now been leading a more or less normal life for some years.

PYREXIA.

Many do not know what constitutes fever, the best method of detecting it, or how to overcome the difficulties of getting careful observations. The best method is to take the temperature per rectum. This is easy in a sanatorium, but difficult for practitioners and tuberculosis officers. If the thermometer is placed in the mouth it should be kept there for at least ten minutes to get a reliable result. A rectal temperature above 98° F. A.M. and above 99·4° F. P.M. should be considered fever, at all events in a man. In most men, in fact, a rectal rest temperature of 98° F. A.M. and 99·4° F. P.M. will be found to be one degree higher than the average temperature of health. One degree lower are readings for oral temperatures. In women it is more difficult to lay down a hard-and-fast-line. In a paper published in 1909 [2] I gave illustrations of two women with evening temperatures a good many points above this level. The one was walking some miles daily; the other was confined to bed. The former married, had three children, and died a year or two ago of another cause than tuberculosis. The latter died within a couple of years of tuberculosis. Children are particularly difficult, as their temperatures are more easily upset. Furthermore, pulmonary tuberculosis and other forms of tuberculosis may upset their temperature for months or off-and-on for years, yet between 6 and 16 a majority of children have good resisting powers against tuberculosis. Sometimes tonsils and adenoids are at the root of ill-health which may simulate tuberculosis.

The other causes of fever without definite signs of physical disease which may constitute pitfalls are: (1) nerves; (2) microbic infections, such as endocarditis, lymphogranuloma, dysenteric liver or liver abscess, perinephric infection, bone infection, nasal sinus infection, typhoid, or paratyphoid; (3) malaria, rheumatic fever, coliform infection, or syphilis—these can often be eliminated by the administration of the proper drugs; (4) neoplasms. I am convinced that neurosis alone can sometimes keep a temperature up as much as 1° F.

FEAR OF TUBERCULOSIS AND PHYSIOLOGICAL LASSITUDE.

A trap into which the doctor is all too ready to fall in refusing to diagnose pulmonary tuberculosis is sometimes dug by the patient himself or his relatives. Amongst many there is a fearful obstinacy in admitting tuberculosis. This is largely a relic of the days when to make the diagnosis spelt the doom of the patient. It is also due to an erroneous idea of the infectivity. When patients, and doctors also, learn that early pulmonary tuberculosis is easily curable in a majority of cases, and that it is not infectious in the ordinary sense of the word, this obstinacy ought to disappear.

Another pitfall is due to the fact that lassitude is sometimes due to more or less physiological causes.

Some years ago I had a young professional woman sent to me with signs of slight fibrosis at one apex; her temperature showed a big swing—namely, from 97°–99·2° F. Besides being tired she was too thin. These symptoms might have been due to pulmonary tuberculosis, but I thought not. I discovered that her work necessitated her getting up early and that she had been going to bed rather late. One of the causes of her lapse from health was undoubtedly the

[2] See THE LANCET, 1909, ii., 852.

cumulative effect of too little sleep. Under an ordinary sanatorium régime she put on 6 pounds in weight and lost her lassitude without developing definite signs of tuberculosis. Now, four or five years later, I learn that she continues well.

The class of case in which lassitude is the main symptom and the other symptoms and signs are inconclusive constitutes a very difficult and most interesting one. These people, usually too thin, more commonly women than men, may have a little dry cough and doubtful temperature readings. They often have an obstinate anorexia, generally with a clean tongue. I have notes of a number of these cases and have followed up several over periods of many years. Very few of those where I have considered pulmonary tuberculosis absent have developed it later in life, but often they remain rather delicate for a year or two. They must be considered from three aspects (1) the presence of tuberculous lesions which, though healed, may break out again; (2) their general metabolism with special reference to the endocrine system; (3) their psychological make-up and condition.

Endocrine Disorders.

We know that the endocrine glands, associated with the sympathetic nervous system, are concerned with the activation of the body for defence. But we know also that an overacting sympathetic and thyroid, for example, can produce tachycardia, shivering, sweating, calcium loss, and increased metabolism. So if we have such overaction with lassitude and thinness suspicions of tuberculosis may be produced. Early Graves's disease is one of the traps to be avoided, especially since a raised temperature is common in this malady. Short of Graves's disease, however, abnormal endocrine interactions may be the cause of ill-health simulating early pulmonary tuberculosis. In the present imperfect state of our knowledge about endocrine imbalance it is not usually possible to set things right by administering appropriate glandular extracts, but this possibility must always be borne in mind.

I recall a difficult and doubtful patient, who took a year or two to get well. She was a young woman of 19 who received tuberculin injections with benefit about a year after she left the Mundesley Sanatorium. Now, in my belief, she never had pulmonary tuberculosis, though it was difficult to be sure, and I believe the tuberculin probably acted, as it may do in some other cases, by so-called protein shock stimulation of the thyroid adrenal apparatus. She was one of those who find it difficult to grow up and neither her intellectual not her psychical state was stable or satisfactory. To-day, years later, she is happily occupied and in good health.

When more is known about basal metabolic rates, when such observations are more frequently made on sanatorium and other classes of patients, when experience with the careful use of insulin in non-diabetic, but anorexic and thin, or obese and phlegmatic individuals has been gained, and when the use of pituitary and thyroid extracts is more scientific, then it will be not only easier to arrive at a diagnosis in some of these doubtful cases, but also easier to treat them satisfactorily. Again, the connexions between exposure to the sun, or other forms of light, and the adrenals and the pituitary are at present not fully understood. Langdon Brown[3] has said of normal people "we are now justified in saying that climatic environment can modify our psychic 'make-up' through the endocrine glands." Let us hope that still more in the future will it be possible to modify an invalid's mental and bodily condition and bring about health by an appropriate régime which will include, amongst other things, a regulation of the climatic environment, not only by the old-fashioned expensive method of change of air and travel but also by heliotherapy. But until more is known about endocrinology, until more clinical observations and experience have been gathered—e.g., on sun-bathing in England for patients with pulmonary tuberculosis—it is certainly best to proceed along the well-known régime, the common-sense lines of hygienic personal living which are often designated "sanatorium treatment." In most of these difficult cases that line of treatment produces satisfactory results, and it may be that even with enlarged knowledge the short cuts to health will be few, and the basis of successful treatment will probably remain as before.

[3] The Endocrines in General Practice, New York, 1927, p. 105.

Psychotherapy and Radiology.

With all these minor degrees of ill-health of doubtful ætiology it is particularly important to realise that the endocrine upset, or at all events the departure from health, is as likely as not psychical in origin. It may not be necessary with most patients to pry into the causes of an obvious mental discontent. But it is necessary to do this in a discreet and kindly manner in the type of patient now under review, or else the physician will not help much to a rapid recovery. Often an unhappy love affair or some other thwarting, perversion, or aberration of the sex instinct leads to an aimlessness in life which may be associated with many of the symptoms usually ascribed to pulmonary tuberculosis. Again, fear of phthisis or fear of loss of a pension, or the vested interest in being the happy recipient of the results of the diagnosis—perhaps erroneous—of pulmonary tuberculosis, may be the origin of the lapse from good health in body and mind. In many instances doctors have fallen into such traps.

Finally, there are many pitfalls in connexion with the diagnosis of pulmonary tuberculosis through over-reliance on and mistakes in the practice of that very helpful aid to diagnosis—radiology. These can mostly be grouped round the following three causes of mistake: (*a*) incomplete coöperation between physician and radiologist; (*b*) imperfect technique; (*c*) ignorance of what constitutes the normal. Of these, the last-mentioned cause of error is the commonest.

PERORAL ENDOSCOPY.

By V. E. NEGUS, M.S. Lond., F.R.C.S. Eng.,
JUNIOR SURGEON FOR DISEASES OF THE THROAT AND NOSE AT KING'S COLLEGE HOSPITAL.

THE following is a record of cases treated at King's College Hospital during four years.

Efficient œsophageal and bronchoscopic examinations and operative procedures entail frequent practice, not only by the surgeon, but also by his assistants. To determine whether the number and variety of cases make this possible and desirable is the object for which a record has been kept; the results show that in this hospital there is ample material for all purposes.

Table I.

—	Ap. 24, 1924, to Ap. 23, 1925.		Ap. 24, 1925, to Ap. 23, 1926.		Ap. 24, 1926, to Ap. 23, 1927.		Ap. 24, 1927, to Ap. 23, 1928.		Total, four years.	
	New.*	Exams.	New.	Exams.	New.	Exams.	New.	Exams.	New.	Exams.
Laryngoscopy	7	13	11	11	5	7	9	13	32	44
Pharyngoscopy	9	10	6	9	6	8	4	4	25	31
Bronchoscopy	4	5	11	34	14	106	14	54	43	199
Œsophagoscopy	42	46	46	55	44	59	44	71	176	231
Total	62	74	74	109	69	180	71	142	276	505

* New cases.

The number of patients for whom peroral endoscopic examinations have been required has remained remarkably constant during the four years beginning on April 24th, 1924, 1925, 1926, and 1927; the figures are 62, 74, 69, and 71 (Table I.). On the other hand, the number of examinations has increased considerably, mainly because of the greater number of bronchoscopies, rising from 5 in 1924 to 34, 106,

and 54 in the three succeeding years. A further cause of increase has been the greater number of œsophagoscopies carried out for treatment of various complaints, the figures being 46, 55, 59, and 71. The year ending April 25th, 1928, shows the smaller total of 142 examinations of all descriptions compared with 180 in the previous 12 months; a decrease in the bronchoscopic treatment of cases of lung suppuration was only partly compensated for by an increase in œsophageal procedures.

Training of Team.

Intelligent and enthusiastic coöperation by registrar, house surgeons, and nursing staff is a necessity; the assistant who controls the position of the patient and the sister or nurse who manages the instruments and swabs must carry out their duties with precision if the operator is to perform his work successfully. Even with a biannual change of senior house surgeon it is possible to maintain an efficient team once the general principles and attention to detail become part of the routine of the clinic. Every house surgeon is, in fact, himself able to pass a bronchoscope on the conscious patient before his term of office is completed. Our junior house surgeon works for six months in the out-patient department, and has opportunities of learning the principles of endoscopy.

Instruments.

At this hospital both Brunning's and Jackson's instruments are used; in almost all cases the latter were found preferable because of facility in sterilisation, lack of clumsiness, the absence of obstruction to the use of swabs, forceps, and other instruments, and the satisfactory arrangements for aspiration of secretions. We find that the lamps of Jackson's instruments are rather delicate, and require frequent attention. An efficient suction pump is a necessity; ours is incorporated in a special bronchoscopic table designed and executed by Mr. Johnston, chief engineer to the hospital (Fig. 1). To protect the eyes a shield has been devised. It consists of a disc of glass which can be rotated so that a clear area is always available.

Anæsthesia.

At King's College Hospital our technique is guided by the teaching of Chevalier Jackson;[1] the well-tested details advocated by him are followed with increasing strictness as time goes on. An example is the greater frequency with which local anæsthesia alone is employed. In our experience the increasing deftness which constant practice gives enables most endoscopic procedures to be carried out without general anæsthesia, to the satisfaction both of the surgeon, and—what is more important—of the patient. Of laryngoscopies, 17 were performed with local and 27 with general anæsthesia; for pharyngoscopies, the figures are 7 and 24; of œsophagoscopies, 111 were under local and 120 under general anæsthesia; and of bronchoscopies, 148 patients had local anæsthesia only, while for 51 a general anæsthetic was thought desirable (total 283 local and 222 general). Morphia, scopolamine, and atropine are given to most of the patients examined under local anæsthesia, but patients who have had two or three examinations usually prefer to have atropine only.

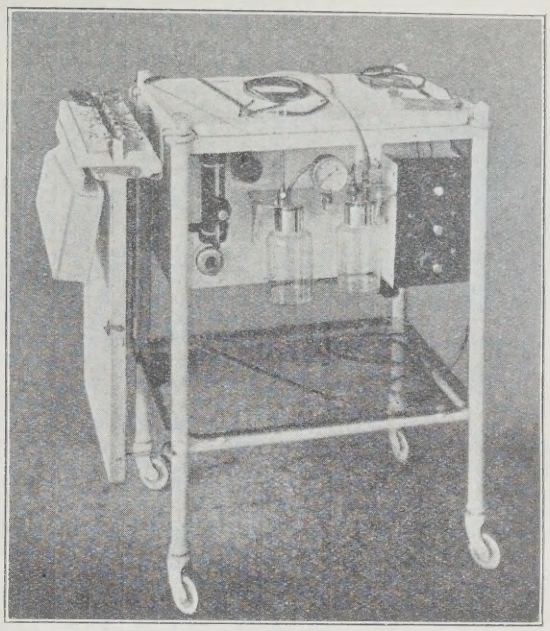
The proportion of those examined under local anæsthetic is increasing as compared with those requiring a general anæsthetic.

Position of Patient.

The Boyce position, as used by Chevalier Jackson, is much preferred in our clinic to the ordinary recumbent or to Mouret's position. The air and food passages can be brought into any desired position; the patient feels less strained; secretions do not overflow into the larynx to cause choking; œsophageal respiration is less; and the discomfort of operative manipulations is lessened. Under local anæsthesia the patient is not held down; he lies still and only needs to have his position maintained by steadying the shoulders. The table, stool, and foot-rest must be at the correct height, a measuring rod being provided to control the position on each occasion.

[1] See THE LANCET, 1926, i., 924.

FIG. 1.—TABLE FOR BRONCHOSCOPY.
(*King's College Hospital Pattern.*)



The frame of the table is a tubular metal construction, mounted on castors, and has a marble top and a lower shelf. The marble top forms the cover to a sound-proof metal case containing an oil-immersed rotary pump, belt-driven by an electric motor. Mounted on the front of the metal case are two suction nozzles, connected through two bottles with the pump—one bottle for collecting the blood and secretions, the second as an overflow vessel to safeguard against any liquids reaching the pump. On the left is a switch controlling the motor and a rheostat to regulate the speed, the resulting strength of the suction being shown on the vacuum gauge which is fixed between the two bottles. On the right are three circular rheostats to control the lights of the bronchoscopes or œsophagoscopes. The above switch and rheostats are all fitted with specially designed metal tops, easy of detachment for sterilising; they can therefore be handled by the operating surgeon. All these, as well as the bottles, gauge, suction nozzles, and terminals for the lamp connecting wires are protected by the overhanging marble top from accidental damage in moving the table from place to place.

On the top of the table are seen a bronchoscope and laryngoscope, together with suction tubing, which can be attached to the bronchoscope or œsophagoscope, or to an independent suction tube. On the left of the table is suspended a container for the light carriers. This is made in two halves, hinged together at the bottom to open in hook form for access to all parts of the interior for cleaning, &c., and is lined with rubber of such construction that the light carriers are held rigidly in position and are kept sterilised by formalin vapour supplied from tablets placed in the bottom of the container. The whole table is self-contained and freely movable from place to place.

The table has been designed by Mr. Negus and Mr. Johnston, chief engineer to King's College Hospital, and was made in the hospital's works department.

Laryngoscopy (see Table II.).

Removal of papillomata from children made up a considerable number of cases, and for them a general anæsthetic was thought desirable. The next most common cause of laryngoscopy was direct examination for carcinoma of the larynx, either to determine the exact extent of the disease or to take a piece of tissue for microscopy. The latter proceeding is carried out easily and without fear of damage to healthy tissues when Jackson's biopsy biting forceps are used.

Pharyngoscopy (see Table III.).

Diagnosis and treatment of carcinomata made up the greater number; diathermy was used in several

cases through a laryngoscope, and in other cases seeds of radium emanation were inserted.

Bronchoscopy.

Table IV. shows clearly that experience derived solely from foreign body work will be very limited and quite inadequate to qualify the operator or his team; in the four years five bronchoscopic examinations were made for foreign bodies and 194 for other reasons.

A large shawl pin, a metal clip, and a wood screw were removed without difficulty; the screw was unsuspected and had led to a tentative diagnosis of whooping-cough (Fig. 2). A small black-headed pin offered a difficult problem, as it was lodged in an anterior ventral branch of the right lower lobe bronchus, of a calibre far too small to allow of the introduction of any bronchoscope. A preliminary direct examination made to confirm this supposition is tabulated as "unsuccessful bronchoscopy for F.B." After sufficient practice on an excised pair of lungs under the fluorescent screen in the X ray room the patient was held in such a position that the forceps, when introduced through a bronchoscope into the mouth of the branch known to contain the pin, entered in the axis of the small bronchus; the pin was grasped under guidance of the screen and was removed. A foreign body not included in the list was a swab which became detached during the bronchoscopic treatment of a patient with multiple cavities in the left lung; it was recovered two days later with some difficulty. This bronchoscopy is purposely excluded from the tables as it was a self-made and preventable job.

Since the date on which this report terminated the number of bronchial foreign bodies has increased. An orange-pip has been removed from a child of 4 without any anæsthetic except morphia gr. 1/10th; the pip had been in situ for over a month. Removal of a molar tooth impacted for one month in the left lower lobe bronchus of a child of 7 took a long time and was particularly difficult; general anæsthesia was used. A third child was admitted with a pin in the mouth of the right upper lobe bronchus, but cured itself by coughing out the foreign body. A fourth object is illustrated (Fig. 3).

* New cases.

A highly satisfactory case was that of a lady who was in a sanatorium because of recurrent hæmoptyses; the cause was a fibroma obstructing the left lower lobe bronchus. The case has already been reported by Dr. L. S. T. Burrell and Dr. R. R. Trail, who referred her to me through the kind agency of Sir StClair Thomson. A preliminary bronchoscopy showed a smooth, rounded neoplasm from which a piece was taken for microscopy. After microscopical diagnosis a second bronchoscopy was performed, and the tumour was nibbled away with long cup forceps through a 7 mm. Jackson's aspirating bronchoscope. This tube was preferred to a larger bronchoscope because of its mobility and its arrangement for continuous suction. At a third examination no remains of the fibroma were seen, and up till now there has been no sign of recurrence.

In three or four cases bronchoscopy was performed to confirm or contradict a clinical diagnosis of carcinoma of the lungs, and in each case direct examination gave a correct report.

A patient with œsophageal carcinoma—treated many times with radium—suffered from attacks of dyspnœa, which suggested ulceration into the trachea, but at bronchoscopy no opening was seen; post-mortem examination showed a fairly extensive involvement of the trachea with s

hole about 1 inch long. Either the rupture took place after bronchoscopy or else the opening was present and was not seen; the latter alternative, although discouraging, is, I fear, correct.

A case first thought to be one of spasm of bronchial musculature was examined again and proved to be due to pressure on the trachea by an aneurysm of the aorta and innominate artery; two other cases of pressure from without were examined, both apparently caused by mediastinal new growths.

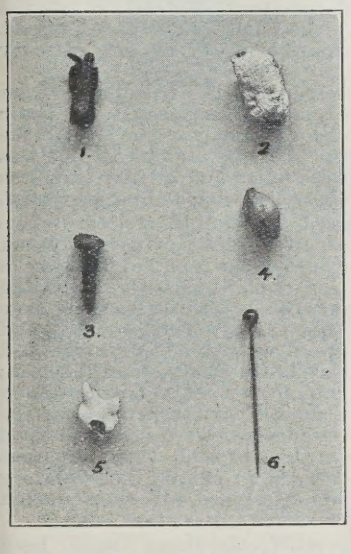
On one occasion the bronchoscope could not be passed owing to the rigidity of the patient; two or three days later and on several subsequent occasions a successful introduction was made under local anæsthetic. Although a general anæsthetic has to be used in certain cases, yet it is far better to dispense with it whenever possible.

Of cases of diffuse suppuration one appeared to have multiple small bronchiectases and was not improved; two others had diffuse bronchitis and were referred for medical treatment.

Of three patients with lung abscess all were cured with ease, thus demonstrating in a limited number of cases that greater success will be achieved when bronchoscopic treatment is commenced early.

One woman who for three weeks had suffered from fever of hectic type following dental extractions was cured after two aspirations combined with local medication, no doubt because of the removal of infected clot associated with efficient drainage and the reduction of granulation tissue: the abscess was in the right upper lobe. A second woman had only one aspiration; she afterwards improved rapidly and left hospital well. High temperature and expectoration of foul pus followed tooth extraction, and her cure was apparently due to the bronchoscopic removal of septic clot. The third patient was a man on whom total laryngectomy was performed; he had considerably raised respiratory rate and high fever commencing on the second day after operation. He was coughing up copious fœtid pus, with signs suggestive of cavitations in the left lower lobe with gangrene of the lung. Through an aspirating bronchoscope stagnant secretions were removed, with almost immediate recovery and the disappearance of the previous physical signs.

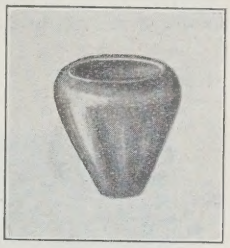
FIG. 2.



Foreign bodies removed from bronchi: (1) Metal clip from a toy; mouth of left upper lobe bronchus of boy aged 7 years. (2) Gauze swab; left lower lobe bronchus of a man. (3) Wood screw; top of left lower lobe bronchus of boy aged 4 years. (4) Orange pip; entrance of left lower lobe bronchus of girl aged 4 years. (5) Molar tooth; left lower lobe bronchus of girl aged 7½ years. (6) Black-headed pin; right anterior distal branch of right lower lobe bronchus of woman aged 24.

Cases of bronchiectatic cavity are grouped together whether originating as primary dilatations of one or more bronchi or as the result of bursting of a lung abscess into a bronchus with secondary expansion of the latter. In either case the rationale of bronchoscopic drainage depends on aspiration of stagnant pus, on dilatation of obstructed bronchi, and on reduction of granulation tissue by local applications of 10 per cent silver nitrate. Lavage was tried on a few occasions but appeared to do more harm than good, and instillation of antiseptics seemed to have the same unsatisfactory result. Unfortunately, in not one of the 19 patients with pus-containing cavities was a foreign body found, although constant search was made. All the patients, in addition to bronchoscopic aspiration and local medication, were made to use a Burney Yeo inhaler, to take creosote, and to employ postural coughing. The group comprises 19 patients on whom a total of 168 bronchoscopies was performed; the least number of treatments for any one patient was 1, and the greatest number was 35. Three patients died during treatment—one of mediastinitis as the result of puncture through the cricothyroid membrane for the injection of lipiodol; one, after temporary improvement, from gangrene of the lung connected with extensive cavities; the third from extensive bronchiectatic cavities in the left lower lobe associated with pleurisy and probably empyema. Four patients were temporarily improved by bronchoscopy, but subsequently relapsed. One, who at first showed no signs of tuberculosis had a large infected cavity in the left upper lobe and was very much better after four aspirations, with normal temperature, diminution of sputum, and gain in weight. Three months after leaving hospital he returned with signs of active pulmonary tuberculosis and died soon afterwards. The case was regarded first of all as one of simple bronchiectatic abscess; bronchoscopy is never performed on patients who are known to have phthisis.

FIG. 3.



Metal cap from de Vilbiss spray; removed from right main bronchus of a man (actual size).

Another patient had a big multilocular cavity in the right upper lobe; he was very much improved by weekly aspiration, for which—like most of our other patients— he came up from his home in the morning, returning in the afternoon. He was kept quite comfortable by 30 bronchoscopic treatments over eight months, but then found he could not himself empty his cavity by postural coughing. Artificial pneumothorax was tried, but without success and thoracoplasty was performed, unfortunately followed by death.

Two other patients improved temporarily but relapsed, and bronchoscopy was discontinued. Three cases were unimproved, two being children for whom general anæsthesia was thought necessary; its use no doubt discounted any benefit derived from bronchoscopy. Four patients were slightly improved; one preferred to leave hospital although she might have been wiser to continue treatment; for the others continuance of aspiration did not seem to be indicated. One patient with extensive cavities in the right upper lobe was very materially improved by aspiration and local swabbing with silver nitrate, but finally thoracoplasty was required because of persistent fœtor uncured by bronchoscopy or by the local use of iodoform or gomenol. Three patients have been very much improved. One had fairly extensive bronchiectatic cavitations in the left lower lobe; he had eight aspirations, the last in June, 1926, and has not required any more since. Two other patients have multiple cavities and have kept well enough without further aspiration, one having had 24 treatments and the other 7.

Conclusions regarding Bronchoscopy.

For success in removal of foreign bodies from the bronchi frequent practice in bronchoscopy is required, and can only be obtained by the treatment of cases of lung suppuration, combined with practice on dissected lungs, rubber tubes, and anæsthetised animals.

A definite diagnosis of the presence or absence of a neoplasm of the lung can almost always be made by bronchoscopy. A simple new growth can be removed, even from a secondary bronchus.

Lung abscesses, if early, can be cured by bronchoscopy. Bronchoscopic aspiration of pus-containing cavities in the lungs should be tried in all cases which do not respond to ordinary medical treatment; the use of drugs and postural drainage should always be combined.

Bronchoscopy alone should not be continued if unsuccessful; the patient should be referred for thoracoplasty or other external operation.

Of the series of cases of bronchiectatic cavities recorded 52·6 per cent. were failures, 26·3 per cent. were relieved, and 21·0 per cent. were successes.

* New cases. Œs. = œsophagoscopy.

As shown in Table V., 231 examinations have been made, 83 in foreign body cases and 148 for other reasons. In 23 patients a foreign body was suspected, but was not found; in a few it may have slipped down in front of the tube. In nine patients an unsuccessful attempt was made at removal; in four of these the object was recovered at a subsequent attempt. The reason for lack of success was: in three cases the use of Mouret's sitting position and the obscuring effect of much frothy saliva; in one intense trauma as the result of previous œsophagoscopy in another hospital; in one slipping of the object after discovery; in one the use of unsuitable forceps; in one transparency and small size of the foreign body; and in one lack of skill in grasping a coin. Seventeen bones were removed; six were fish bones, eight were from meat, and three from poultry (Fig. 4). Disimpaction of an embedded point was in many cases difficult, particularly when attempted upon the sitting patient, in whom the large amount of frothy saliva and mucus, so commonly seen, caused most unpleasant choking. An observation often made may be repeated here—namely, that if a patient is convinced that a bone is stuck in the throat the chances are strongly in favour of the correctness of the statement.

All the foreign body cases—including those in the bronchi—were successful and in none did untoward symptoms occur—that is to say, all the patients went home with the cause of their trouble brought to the surface or with an assurance that no extraneous object was present in the air passages, pharynx, or œsophagus. Coins were frequent, almost always at the level of the crico-pharyngeal fold of young children. As a rule, it may be said that an anæsthetic causes a child a great deal more fear and discomfort than does the removal of the foreign body, which can be effected in a few seconds if the operator and his assistants are well practised. Twenty-one in all were removed. In two instances the coin had been in situ for three months and the extensive granulations made localisation difficult; in neither case was there any subsequent cicatricial stricture (tabulated as "negative œsophagoscopy after F.B."). Only one safety-pin has been encountered and that with the point down, so that no difficulty was met with; the ring was grasped by rotation forceps and the pin was removed with the point trailing. No difficulty was experienced with other foreign bodies.

Of patients complaining of dysphagia not caused by foreign body 18 were found on examination to be without any organic lesion. On two occasions the œsophagoscope could not be passed because of the rigidity of the patient under local anæsthesia; in each case a general anæsthetic allowed an examination to be made.

A young female patient with pain in the crico-pharyngeal fold, relieved by swallowing, was cured by dilatation with a big œsophageal speculum; in view of the great force exerted by the muscle band in its normal state of contraction it is surprising that no more cases have presented themselves. Of cases of arrest of food at the level of the diaphragm one was treated by dilatation with Jackson's bougies and also with Brown Kelly's pattern of hydrostatic bag because of some inflammatory contraction at the diaphragmatic hiatus; these procedures were thought necessary before the routine use of Hurst's mercury bougie.

Of patients with pressure on the œsophagus from some external cause one was suspected of aortic aneurysm associated with carcinoma at the level of the crossing of the left bronchus. An œsophagoscope was passed as far as the aortic bulge and a Hill's tube was slipped through the stricture, with temporary relief.

In the group classed as simple stricture two patients had dysphagia after total laryngectomy and in both there was a rupture of the repaired pharynx in the site of the operation scar, apparently associated with cicatricial stenosis. Of six other cases there were histories of 20, 17, 15, and 13 years', nine months' and three weeks' duration; all were much improved and swallowing of solids was fairly easily re-established; in one or two cases Plummer's thread-guided method was used. Four cases showed strictures close to the crico-pharyngeal fold, while two were near the level of the left bronchus. One patient with apparent carcinoma was proved to be of simple inflammatory type by the examination of a piece of tissue removed with long forceps of Jackson's type.

Forty-six patients with carcinoma have been examined; although a correct diagnosis may often be made without the use of the œsophagoscope, it is in our opinion invariably necessary to make a direct examination. As already noted, one woman with all the clinical and X ray appearances of carcinoma was found by œsophagoscopy to have a simple inflammatory stricture; she was cured. Two other patients had the symptoms, clinical and X ray appearances of non-malignant obstruction at the level of the diaphragm, but both were proved to have carcinomata, as demonstrated in microscopical sections. A correct diagnosis is very necessary, as such forms of treatment as the mercury bougie are definitely contra-indicated in cases of malignant new growth. Of 46 cases, 11 were at or close to the crico-pharyngeal fold, 8 in men and 3 in women; 24 were at or near the middle of the œsophagus, 22 in men and 2 in women, 1 of whom was not definitely proved to have a carcinoma; 11 were at the level of the diaphragm, 9 in men and two in women. Of the total patients 39 were men and 7 were women. The ages of patients were as follows: of

growths at the top, the youngest man was 50, and the youngest woman 58; the eldest man was 84, and the eldest woman 70. Growths at the middle occurred at 48 in the youngest man, and at 63 in the youngest woman; at 77 in the eldest man, and at 73 in the eldest woman. Of growths at the bottom the youngest man was 44, and the youngest woman 46; the eldest man was 77, and the eldest woman 70.

Of those growths at the top of the œsophagus none of the male cases appeared suitable for operation. Of the women two had typical post-cricoid neoplasms; one had total laryngectomy and pharyngectomy, but, owing to the wide extent of the growth with involvement of the thyroid gland, death took place next day. A second patient refused operation and the third appeared unsuitable. For this type of case either lateral pharyngectomy by Trotter's method or pharyngectomy combined with laryngectomy are advocated; failing these procedures the patient is referred for gastrostomy. For carcinomata near the middle of the œsophagus various measures have been employed, all palliative, but some of them enabling the patient to swallow fairly comfortably until he dies of asthenia or of lung complications, without the unpleasant necessity of gastrostomy feeding. Simple dilatation under vision with Jackson bougies has given considerable relief; Plummer's thread-guided method has also been used, but in some cases there has been difficulty in getting the thread to pass. One patient devised the method of piercing a carbolic lozenge and attaching the thread to it; after being swallowed, the lozenge partly dissolved until it was small enough to pass through the stricture. Souttar's tubes have been introduced seven times and often with relief; the difficulty has been to keep them in place. In two patients death took place one and three days respectively after introduction from general asthenia and not from perforation of the œsophageal wall.

Radium has been used on 12 patients, the least number of milligramme-hours being 800 and the most 3700, with figures in others of 2400, 1750, and 1600.

A method recently employed was to apply 100 mg. of metallic radium or a tube of radon in a silver container attached to a whalebone staff; below the container was screwed a large olivary bulbous end, perforated for a thread as in Plummer's method (Fig. 5). The bougie is guided by the thread through the malignant stricture, and is pulled up until its shoulder taps against the lower end of the stricture; the radium is then in correct position in the growth and is retained there for two or three hours. The procedure can be repeated daily without much discomfort. One patient had 22 applications; he died of extension of the growth above the level of the part irradiated, the trachea being involved. Alterations in the applicator have now been made to allow of better distribution of the radium.

Growths at the lower end of the œsophagus were in one or two instances primary, but some spread up from the stomach; gastrostomy was the routine

procedure, or jejunostomy if the stomach was extensively invaded. A piece of tissue can be taken without danger in suitable cases in order to establish a definite diagnosis. One patient appeared to have suffered from œsophagectasia, caused by a neurosis of the lower end of the œsophagus. Later he had an inflammatory stricture—no doubt as the result of stagnation of food—as seen with the œsophagoscope. It was only after some months that malignant changes were suspected and were confirmed by microscopy, thus emphasising the necessity of frequent direct inspection.

Conclusions.

All manner of foreign bodies can be retrieved by the route of which they entered—that is to say, by œsophagoscopy.

Simple strictures respond very well to treatment, but direct examination is required.

Even though the diagnosis of carcinoma can generally be made correctly without œsophagoscopic examination, yet mistakes can occur. Therefore direct inspection and a positive diagnosis are always necessary.

Summary.

The number and variety of cases requiring endoscopic treatment in a large general hospital are sufficient to warrant the purchase of an efficient set of instruments and to make constant practice worth while. Attention must be paid to detail, particularly in preparation for the removal of a foreign body. The removal of foreign bodies does not by itself give sufficient practice, either in œsophagoscopy or bronchoscopy; the best road to success is to follow minutely the rules laid down by a master of the subject, such as Dr. Chevalier Jackson.

URINE PROTEINS IN NEPHROSIS, PREGNANCY, AND MYELOMATOSIS.

By LESLIE FRANK HEWITT,* PH.D., B.SC. LOND.

(*From the Hale and Dunn Clinical Laboratories, London Hospital.*)

SEVERAL explanations of the origin of urinary proteins have been suggested. The idea that proteins of the food are excreted by the kidney, either unchanged or after partial digestion, has been generally abandoned, and it is now accepted that urinary albumin in nephrosis is identical with serum albumin. The interesting results of Hynd (1925) support this view, but he himself admits that he did not purify the proteins satisfactorily. The present author has shown (1927 [1]) that, for determination of the optical rotatory power of proteins, careful purification is necessary, and particularly the removal of lipins under conditions precluding denaturation. When efficient purification with suitable precautions is effected, concordant and characteristic values for the rotatory powers of proteins are obtained. Hynd obtained values ranging from $-49°$ to $-66°$ for the specific rotation of proteins from the urine of patients with chronic nephritis and albuminuria of pregnancy, and values of from $-34°$ to $-41°$ and from $-49°$ to $-59°$ in eclampsia. He concludes that serum albumin (rotation $= -52·9°$) is excreted in nephritis, albuminuria of pregnancy, and some cases of eclampsia, but that in other cases of eclampsia lactalbumin (rotation $= -41·2°$) is excreted in the urine owing to some derangement of milk secretion. No clinical differentiation was made between the two classes of eclampsia, which were apparently identical in symptoms. Owing to the small quantities available, Hynd did not free the proteins from lipoids, which seriously affect the rotation, and they may have been contaminated with nitrogenous substances such as uric acid, which seems to cling tenaciously to protein precipitates and which decreases the apparent rotatory power of the protein by increasing the nitrogen-content of the solution. Further, the solutions examined were very dilute; in general the rotations measured were only about $0·4°$, and in one case only $0·08°$. This, of course, increases the experimental error, perhaps in some cases to nearly 30 per cent. It would also seem possible that lactoglobulin and caseinogen might accompany the milk albumin if the milk secretion were deranged and lactalbumin passed into the blood stream and thence through the kidney. No one has observed this phenomenon.

Thomas, Schlegel, and Andrews (1928) suggest that in albuminuria the first stage is liver damage caused by circulation of toxins; liver proteins pass into the blood stream and leak through the kidney into the urine. The kidney becomes damaged by the passage of foreign protein and serum proteins then leak through the kidney into the urine. Our results suggest that no abnormal liver albumin occurs in the urine of nephrosis, albuminuria of pregnancy, and eclampsia, and the globulin fraction, where liver proteins might occur, is generally very small. In addition, it is shown that the passage of some foreign proteins through the kidney for long periods does not appear to cause leakage of serum albumin. In the present paper the purification and examination of the proteins in the urine of a few cases of nephrosis, albuminuria of pregnancy, and eclampsia, and some details of cases of myelomatosis are described.

Preparation of Urine Albumins.

In some cases dilute urines were first concentrated by ultrafiltration as previously described (Hewitt, 1927 [2]); in others the fresh urines, after filtration through filter paper, were subjected to the following processes, all conducted as expeditiously as possible to avoid proteolytic, bacterial, and chemical changes in the protein.

Instead of adding sufficient ammonium sulphate crystals to saturate the urine—not a very satisfactory process—saturated ammonium sulphate was added to the urine up to about 70 per cent. saturation, and the pH was adjusted to 4·7 by adding 10 per cent. acetic acid. In this way all the albumin was precipitated and there was no difficulty in dissolving crystals. Next morning the precipitate was filtered off on a buchner funnel and dissolved in a small quantity of water, and the solution was neutralised, cooled to 0° C., and added drop by drop to 7–10 volumes of a mixture of absolute alcohol (7 vols.) and ether (3 vols.) cooled to $-15°$ C. After being allowed to stand in a mixture of ice and salt at low temperature for 1–2 hours the precipitated proteins were filtered off on a chilled buchner funnel in the ice chest, washed thoroughly with an alcohol-ether mixture and with ether, both being cooled to $-10°$ C. and then transferred rapidly to a Soxhlet thimble and extracted with ether for two hours, sodium metal being placed in the extraction flask to prevent any extracted alcohol from refluxing. The dried proteins are not denatured by ether. The presence of ammonium sulphate in the protein facilitates and accelerates the filtration. After two hours' extraction the ether and sodium were renewed and the extraction continued for a further 18 hours. The proteins were then transferred to a vacuum desiccator and dried in vacuo over sulphuric acid for 48 hours. After being allowed to remain in contact with the atmosphere for 24 hours the proteins dissolved readily in water, leaving a small amount of insoluble material (uric acid, &c.). The ammonium sulphate concentration was then adjusted to 50 per cent. by addition of saturated ammonium sulphate solution. The precipitation was allowed to continue overnight, and then the precipitated globulins (only a small proportion of the total proteins) were filtered off on a buchner funnel, a hardened filter paper being used. The albumin in the filtrate was precipitated by adding a further quantity of saturated ammonium sulphate solution and adjusting the reaction to pH 4·7. The precipitation was allowed to continue overnight, and then the precipitated albumin was filtered off on a hardened filter paper in a buchner funnel. After two repetitions of this precipitation the albumin was dissolved in about 12 c.cm. of water and placed in a tested collodion sac sealed by means of rubber pressure tubing attached by a rubber band and closed by a piece of glass rod. The proteins were dialysed against distilled water for at least ten days,

* Working under the auspices of the Freedom Research Fund.

the outside fluid being changed constantly the first day and then daily. At the end of this time all the ammonium sulphate had dialysed out. The solution was then filtered through a Seitz filter, a clear, sterile fluid with a yellow or brownish colour being obtained.

Optical Rotatory Powers.

Rotations were determined by means of a Schmidt and Haentsch polarimeter with a tripartite field and a direct vision spectroscopic eyepiece fitted by Hilgers. The light sources employed were a mercury-vapour lamp ($\lambda = 5461$—5780 A.U.) and a Nernst lamp with colour filter ($\lambda = 6660$ A.). In Tables I. and II. rotations are quoted for a 1 dm. tube, except where otherwise stated.

TABLE I.—*Observed Rotations.*

Case.	Protein concentration (percentage)	$\alpha\lambda$		
		λ 6660	λ 5780	λ 5461
1	2·00	−1·00°	−1·33°	−1·54°
2 (*a*)	3·29	−1·62°	−2·28°	2·63°
2 (*b*)	1·74	0·79°	1·17°	1·35°
2 (*c*)	1·26	0·63°	0·90°	1·02°
3	3·99	1·91°	2·75°	3·14°
4	2·89	1·31°	1·96°	2·17°
5	4·87	2·39°	3·38°	3·80°
6	3·78	1·67°	2·60°	2·94°
7	4·50	0·82°*	1·21°*	1·38°*
8	2·60	1·15°	1·67°	0·79°*

(*a*), (*b*), (*c*) = specimens.
* Denotes 4 cm. tube used in place of 1 dm. tube.

TABLE II.—*Specific Rotatory Powers.*

Case.	Diagnosis.	$[\alpha]\lambda$ $\lambda = 6660$	5780	5461 A.U.
1	Nephrosis.	−50·0°	−66·7°	−77·0°
2 (*a*)		49·2°	69·2°	79·9°
2 (*b*)		45·3°	67·1°	77·4°
2 (*c*)		50·0°	71·5°	80·9°
3		47·8°	68·9°	78·6°
4		45·3°	67·8°	75·1°
5	Albuminuria of pregnancy.	49·1°	69·4°	78·0°
6		44·2°	68·8°	77·8°
7	Eclampsia.	45·6°	67·3°	76·7°
8		44·2°	64·3°	76·0°
Mean value (urine albumin)		−47·1°	−68·1°	−77·7°
Serum albumin (Hewitt, 1927 [1])		−47·3°	−67·0°	−78·1°

It will be seen that the optical rotatory powers of the urinary albumins in nephrosis, albuminuria of pregnancy, and eclampsia were, within the limits of the experimental error, identical with that of serum albumin. The rotatory powers for green light ($\lambda = 5461$ A.U.) are those most accurately determined. It is more difficult to match the filtered red light and the yellow line is a doublet.

The refractive indices of urine and serum albumin are not distinguishable (Table III.).

TABLE III.

—	—	T° = 17° C. Concentration per cent.	n_D of soln.	—	Calculated n_D of 100 per cent. protein.
Case 7.	Eclampsia.	4·5	1·3422	0·0090	1·583

Ser. alb.	Normal.	7·45	1·34835	0·01515	1·586

Mr. Smith, of the London Hospital Medical College, has examined the ultra-violet absorption spectra of some of these preparations and found them indistinguishable from serum proteins. A few notes on the cases follow (Table IV.).

TABLE IV.

Case.	Sex.	Age.	Blood-urea.	Urine urea concentration.	P.S.P. excreted in three hours.	Albumin volume in urine.
			Per cent.			
1	M.	34	0·041	2·16	47	Three-quarters.
2	M.	26	0·050	>2·0	>50	Half.
3	F.	22	0·070	2·0	46	—
4	M.	31	0·138	1·0	Trace.	Half.
5	F.	23	0·040	>2·0	>50	,,
6	F.	27	0·030	>2·0	>50	,,

CASE 7.—Female aged 34. Eclampsia. No previous miscarriage; two children. Dec. 3rd, 1927: eight months pregnant; blood pressure, 200. Unconscious and twitching; urine solid with albumin, one fit. 4th: improved after stomach and colon wash. 5th: normal fœtus born dead. 7th: urine—albumin half volume. Blood-urea, 0·021 per cent. Urine-urea concentration, 3·84 per cent. 11th: blood pressure, 150. 13th: albumin cloud only.

CASE 8.—Female aged 30; eclampsia; one child; no previous miscarriage. Dec. 6th, 1927: 32 weeks pregnant, no albuminuria or vomiting; some hæmorrhage. Blood pressure, 120. Jan. 5th, 1928: further hæmorrhage; vomiting; albumin two-third volume; blood pressure, 220; slight œdema; two fits. Fœtus born in rigor mortis. 9th: slight trace of albumin; blood pressure, 160/115. Urine samples examined were taken just before and after fits.

Myelomatosis.

CASE 1.—Male aged 46. Spontaneous fracture of right tibia. X ray examination showed typical moth-eaten appearance of bones, especially femora, pelvis, and skull. Lost 21 lb. in two years. Examination of the blood on various occasions indicated a severe degree of secondary anæmia, but the differential counts were not significantly abnormal. The serum calcium (12·8 mg. per 100 c.cm.) was slightly high, as might be expected in a case of bone breakdown. The serum proteins were normal in amount: albumin, 4·35 per cent.; pseudoglobulin, 1·31 per cent.; euglobulin, 0·65 per cent.; total, 6·31 per cent. A trace of Bence-Jones protein was, however, detected in the serum. None of the abnormal protein was detected in the cerebro-spinal fluid, which was normal in composition (determined by the method previously described, Hewitt, 1927 [3]): albumin, 0·031 per cent.; globulin, 0·003 per cent.; total, 0·034 per cent. Blood fragility and clotting time were normal. It would be expected, and it was found, that since Bence-Jones protein is excreted by the kidney some must appear in the blood stream. The non-appearance in the cerebro-spinal fluid is also not surprising. Considerable amounts of the protein have been passed continuously into the urine (Table V.).

TABLE V.

Date.	Volume of urine in c.cm.	Protein per cent.	Quantity passed in 24 hours.
19/10/26	700	2·0	14 g.
20/10/26	800	1·5	12 g.
11/11/26	2500	0·64	16 g.
30/11/26	3600	0·68	24·5 g.
8/11/26	2600	0·56	14·6 g.
6/ 1/27	4000	0·64	25·0 g.
8/ 4/27	3250	1·09	35·4 g.

Large quantities still appear continuously in the patient's urine, but from 1926 until the present day no albumin has been detected and, although renal functional tests indicate kidney damage, the damage is not becoming more marked but is rather decreasing (Table VI.).

TABLE VI.

Date.	Blood-urea per cent.	Maximum urea concentration in urine, per cent.	Percentage P.S.P. excreted in three hours.
29/11/26	0·067	0·54	17·5
5/ 4/27	0·054	0·72	27·5
10/ 2/28	0·079	1·68	34·4

Continuous passage of large quantities of a foreign protein does not therefore appear to cause leakage of serum albumin into the urine. The patient is still alive and not confined to bed.

CASE 2.—Female aged 66; eight children alive and healthy. Several spontaneous fractures caused by trivial accidents. X ray appearance showed extensive rarefaction of bones, including femora, humerus, skull, ribs, left shoulder (where a fracture had occurred), eighth dorsal vertebra, and collapse of head of tibia and fibula. Blood examinations indicated a slight degree of anæmia. The serum calcium was normal—i.e., 9·4 mg. per 100 c.cm. Less Bence-Jones protein was found in the urine than in the previous case, but it has always been and is still present continuously (Table VII.).

TABLE VII.

Date.	Urine volume in c.cm.	Protein per cent.	Quantity passed in 24 hours.
10/10/27	300	0·8	2·4 g.
3/28	200	0·7	1·4 g.

On no occasion has albumin been detected in the urine, and renal functional tests indicate little kidney damage if any.

Date.	Blood-urea.	Maximum urea concentration in urine.	P.S.P. excreted in three hours.
20/3/28	0·03 per cent.	1·68 per cent.	55·6 per cent.

The passage of Bence-Jones protein has not caused progressive kidney damage, nor have detectable amounts of albumin appeared in the urine. The patient is confined to bed.

CASE 3.—Male. Typical X ray appearance. Bence-Jones protein excreted continuously in urine for several years; no albumin detected. The patient was able to carry on a practically normal existence.

CASE 4.—Female aged 51. X ray examination showed typical rarefaction of scapulæ, clavicles, ribs, vertebræ, and most other bones. Pain in back and legs for four years. Blood examination showed some degree of anæmia and slight poikilocytosis and anisocytosis, but no nucleated erythrocytes. Considerable amounts of Bence-Jones protein were excreted. The patient was confined to bed and died on discharge from hospital.

CASE 5.—Male aged 59. Pain in back and under sternum. X ray examination revealed slight rarefaction of upper end of the medulla of the right radius, and of the occipital region of the skull, and some expansion of the sternal end of the right ribs. Splenectomy was performed, and the spleen appeared enlarged but not otherwise abnormal. The blood examinations showed lymphatic leukæmia and some anæmia. Serum calcium was within the normal limits: 9·71 mg. per 100 c.cm., and the blood fragility was normal. A considerable amount of Bence-Jones protein appeared continuously in the urine.

A detailed study of the properties of Bence-Jones proteins is being made, and will be reported subsequently. In every case the urine contained protein, which coagulated on heating at an abnormally low temperature, but in Cases 1 and 2 the protein did not redissolve except under very special conditions. The failure of a urine protein to redissolve on boiling the solution does not therefore exclude the possibility of myelomatosis. The proteins possess properties similar to pseudo-globulin, and different proteins appear to be excreted in different cases.

Discussion.

The albumin in the urine of patients with nephrosis, albuminuria of pregnancy, and eclampsia are indistinguishable from serum albumin. In these diseases, therefore, kidney damage occurs and serum albumin leaks through unchanged. The consequent reduction in serum albumin and the lowering of the osmotic pressure of the blood account for the œdema. In the two cases of eclampsia studied no evidence was obtained of the presence of lactalbumin in the urine as found by Hynd (1925). Admittedly the number of cases is very small indeed, but there seems no reason why milk albumin should be excreted in some cases and serum albumin in other cases clinically indistinguishable from them. Also the absence of any appreciable amount of caseinogen and lactoglobulin from the urines studied by Hynd may support this view.

The fact that continuous passage of a protein—i.e., Bence-Jones protein—through the kidney for long periods does not cause progressive kidney damage or leakage of serum proteins is evidence against the view that albuminuria in general begins by damage to the liver and leakage of liver proteins through the kidney, and that this causes kidney damage resulting in leakage of serum proteins.

The origin of Bence-Jones proteins remains obscure, particularly since they appear to have different properties in different cases and are not all dissolved on boiling.

Conclusions.

1. In the few cases studied no difference could be detected between serum albumin and urinary albumin excreted in nephrosis, albuminuria of pregnancy, and eclampsia. In these cases, therefore, serum albumin probably leaks through the kidney unchanged.

2. Passage of large quantities of Bence-Jones proteins through the kidney for long periods does not produce progressive kidney damage, and does not appear to cause leakage of serum albumins. It is probable, therefore, that the passage of foreign proteins through the kidney does not cause leakage of serum albumin.

3. Bence-Jones proteins differ in properties and are not all soluble in boiling solution. The protein appears to be present in the serum but not in the cerebro-spinal fluid. The albumin and globulin content of the blood and cerebro-spinal fluid are not abnormal in myelomatosis.

The author is indebted to Dr. Lewis Smith, Surgeon-Commander F. G. Hitch, R.N., Dr. J. W. McNee, Dr. Janet Vaughan, and the physicians and surgeons of the London Hospital for permission to quote the cases described, and to Dr. J. R. Marrack for his help and interest.

THE MECHANISM OF THE STOKES-ADAMS SYNDROME.

AS ILLUSTRATED BY THREE CASES.

BY HENRY L. HEIMANN, M.D., M.R.C.P. LOND.,

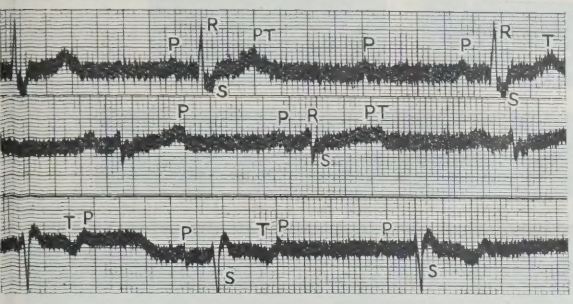
EXTRA HON. PHYSICIAN, JOHANNESBURG GENERAL HOSPITAL; CLINICAL LECTURER, UNIVERSITY OF THE WITWATERSRAND.

DURING the years 1925–1926 three cases exhibiting the Stokes-Adams syndrome were admitted to the Johannesburg General Hospital. The electrocardiographs of these patients throw some light on the mechanism which produces the syndrome.

CASE 1.—A farmer, aged 66, was admitted to the Johannesburg General Hospital under Dr. A. Watt on Sept. 28th, 1925, for "rheumatism." This had crippled him for the preceding ten months, and the enforced inactivity accounted for the absence of cardiac symptoms. His heart was slightly enlarged to the left, but there were no thrills or murmurs. The blood pressure was 160/95, Wassermann negative, and urine normal. The pulse-rate was 40, sometimes irregular, and on this account an electrocardiograph was taken. This showed a varying 2/1 and 3/1 heart-block (see Fig. 1) with left ventricular preponderance. The auricular rate was not regular in this graph. On Oct. 20th the teeth were removed on account of root sepsis. On the 30th complete auriculo-ventricular dissociation was present, with a ventricular rate of 36 per minute. Adrenalin hydrochloride hypodermically made no difference to the amount of block in the tracing. It was noticed that there were progressive changes in the character of the first ventricular complexes, and that left bundle block set in. Apparently an active myocarditis was in progress.

On Nov. 10th the patient had the first of a series of Stokes-Adams attacks, which occurred daily until Dec. 10th. These were typical in form and corresponded to a complete cessation of pulse. Some attacks lasted a few moments, others as long as 42 seconds. At one time there were as many as 20 attacks in one day. Fig. 2 shows complete cessation of ventricular action in lead III. and also exhibits a change in the Q R S complexes in leads I. and II. when compared with Fig. 1. Chart I. is a reproduction of a bromide paper record taken over a long period in the same day. This curve, and a similar one obtained in Case 2, were taken

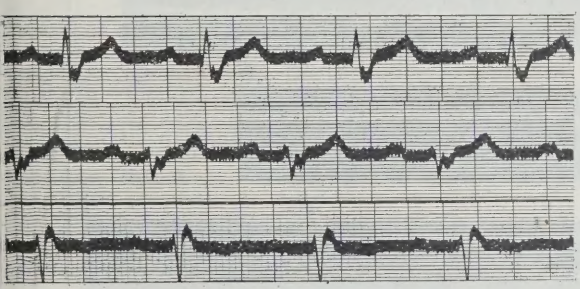
FIG. 1 (Case 1).



2/1 and 3/1 auriculo-ventricular block. (Time 1/5 and 1/25 sec.)

by applying the electrodes to the right arm and left leg of the patient in bed (lead II.). They are read from right to left; the scale is approximately 1 in. to 4 secs. in this case. The first row A D of this record shows a standstill of the ventricles for a period of 15 secs., interrupted only by two dissimilar extrasystoles B and C. This is succeeded in the second row by a period of 2/1 block E F and 1/1 block G H. Both the auricular and ventricular rates vary in these two portions of the curve. The tracing I R is continuous. There is inactivity of the ventricle from I to Z, a period of 34½ secs. The period I J shows regular auricular beats interrupted by fibrillary movements. J X is a fit movement followed by the period X K L where only auricular beats occur. In the period L P there are three fit movements, the first of which lasts 4/5 secs., the second

FIG. 3 (Case 1).



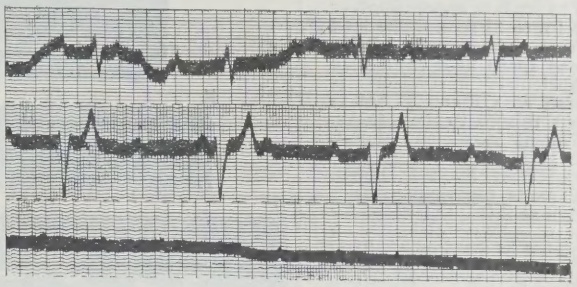
one 3/5 sec., and the third one 7 2/5 secs. These are separated at N and O by auricular beats, each for periods of 2 1/5 secs. At Z 2/1 block again sets in, with the type of Q R S complexes prevailing that day. This tracing shows clearly that the fits occur during periods of ventricular inactivity.

The fibrillary movements from I to J cannot be instrumental in character, as they are not apparent in the ventricular complexes. The auricular rate in the curve varies considerably only at G H. During the days that Stokes-Adams attacks were present (as gauged from cardiographs not published), the auricular rate varied from 72 to 88 per minute. Auricular rate had no influence in determining 2/1 or 3/1 block. The auricular rate at the beginning of the whole series of photographs was 80 per minute, and at the end of the series 66 per minute. Later cardiographs show reappearance of Q R S complexes similar to those present on admission. The last tracing (cardiograph 3) shows 1/1 rhythm, the P/R interval only being lengthened. The last Stokes-Adams attack was on Dec. 10th, about five weeks before discharge from hospital. The blood pressure had fallen from 160/95 to 135/75, the block was 1/1 consistently, and the patient's general health was greatly improved.

Drug Treatment.—Atropine sulphate, gr. 1/150, seemed to be more help than adrenalin hydrochloride, and was given twice a day from Nov. 22nd to Dec. 9th, 1925, and thereafter when necessary. Thyroid and barium chloride were also exhibited.

There was, therefore, on admission old myocardial mischief which went through a period of acute

FIG. 2 (Case 1, same day as Chart I.).

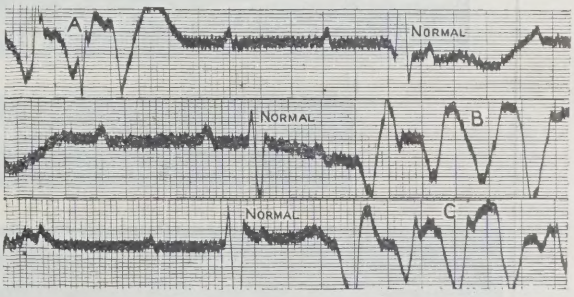


Complete ventricular standstill, third lead. (Time 1/5 and 1/25 sec.)

exacerbation on both clinical and electrocardiographic evidence. The acute exacerbation cleared up and the cardiac condition improved. The question of its association with oral sepsis arises.

CASE 2.—Female, aged 57, had been admitted with cystitis during the year 1920. In 1926, three months before admission into Dr. Watt's ward, she had suffered from shortness of breath. Shortly before admission she herself had noticed irregularity of the heart-beat and had had some attacks of unconsciousness. On August 13th, 1926, while she was attending as an out-patient for her medical condition, her pulse was found to be beating at the rate of 40 to the minute. Electrocardiographic examination showed that 2/1 auriculo-ventricular block was present.

FIG. 4 (Case 3).



Paroxysmal ventricular fibrillation. (Time 1/5 and 1/25 sec.)

Besides the breathlessness there were no other symptoms or signs of cardiac decompensation.

She was admitted to hospital for investigation on Sept. 17th, 1926. There was no obvious enlargement of the heart and no thrills or bruits were detected. There were, however, many dropped beats, and a short sharp sound was heard midway in the ventricular pause and was most marked at the fourth interspace, just to the left of the sternal margin. The duration of the sound was notably less than that of the first heart sound. It was presumed that this was an auricular sound, on account of its position in the cycle and also on account of the presence of 2/1 block according to the electrocardiographic record taken at the time.

On Sept. 25th she had six fits of the Stokes-Adams variety, one lasting two minutes. During the long attack Dr. Watt injected 10 minims of adrenalin hydrochloride into the left ventricle and the patient revived.

On Sept. 26th, 1926, she had three attacks; on the 27th, two; on the 28th, three; and on Oct. 4th she had six attacks, each lasting from 10 to 40 seconds.

During an attack the patient became flushed and then very pale and breathed very heavily. Loss of consciousness with fit movements followed, the pupils became dilated, the conjunctival reflex was lost, and the respiration became slower. The face flushed once more on the first beat.

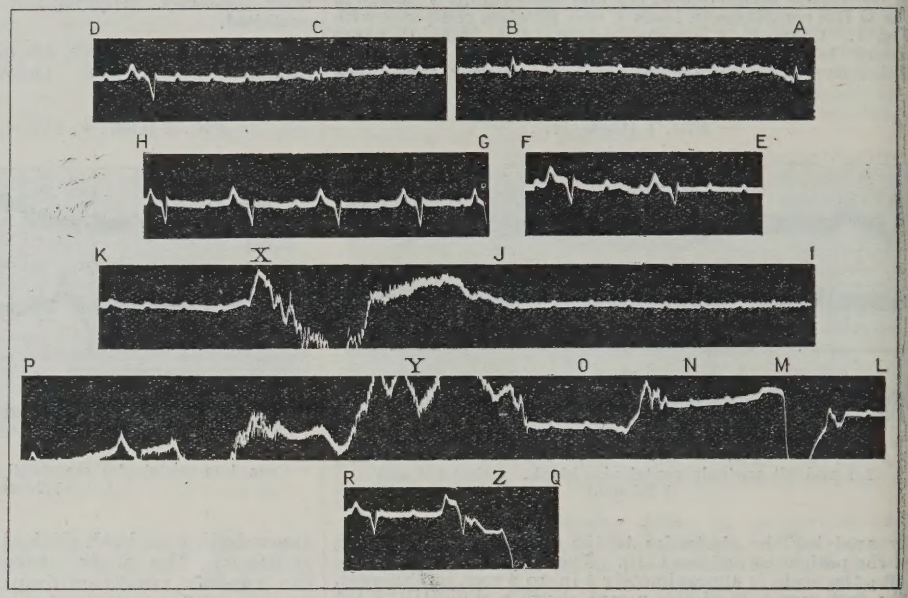
Cardiographs taken during the hospital period showed a progressive change in the Q R S complexes.

Chart II. is a reduced copy of a bromide paper tracing taken on Sept. 28th, ten days before death. The scale is approximately 3 in. to 11 secs. The lead from right arm to left leg was again used (lead II.). Auricular fibrillation is seen at X F and Y, but is not related to the attacks. The fit movement at K L is succeeded by 1/1 block and then by 2/1 block. There is ventricular standstill at Z O P Q (except for two extrasystoles) for a period of 8 1/5 secs. This is followed by a fit movement Q R. Complete block ensues in which the auricular rate is not regular, and this passes into 2/1 block, the dominant rhythm. There is slowing of the ventricle when ventricular standstill has passed away. Ectopic ventricular beats occur at times during the tracing, but they are not related to the attacks, nor do they conform to any Q R S complexes seen in graphs taken previously.

From admission onwards albumin, blood, and pus were found daily in the urine. The infecting organism proved to be a streptococcus which presumably caused the myocarditis. The Wassermann reaction was negative.

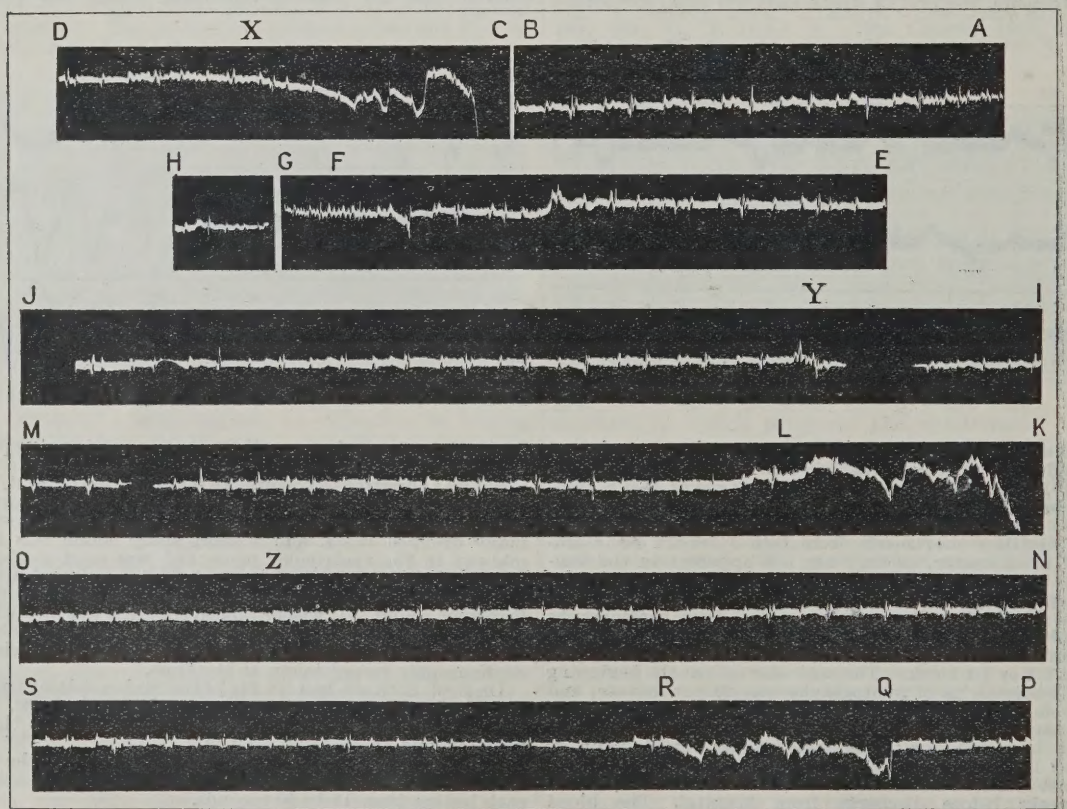
Drug treatment similar to that in the first case was of no avail. She died on Oct. 7th, 1926. No post-mortem examination was allowed.

CHART I.



CASE 3.—Female, aged 46, complained of difficulty in breathing and palpitation for three weeks before admission under Prof. O. K. Williamson. On admission her pulse-rate was 60 and dropped to 30, and finally settled down to a rate between 28 and 30. Her systolic blood pressure was 195 and the heart was greatly enlarged to the left, but there were no valvular murmurs. She had the typical spaces in

CHART II.



the rhythm denoting dropped beats of a partial heart-block. During her stay in hospital she had several attacks of unconsciousness, and the electrocardiograph showed complete auriculo-ventricular block with a right bundle lesion. Later cardiographs show a change of state of the ventricular complexes in lead II., and this is evidence once more of an acute myocarditis.

She was discharged and readmitted after a period of six weeks, as she had had recurrence of the unconscious attacks for a week previously. Her attacks were characterised by breathlessness, cyanosis, and a period of unconsciousness of a few seconds (generally about ten), during which the pulse was imperceptible. She had several attacks during the next few days and died in one of them. No post-mortem was allowed.

Fig. 4 shows three small attacks, A, B, and C. It will be noted that these are totally unlike the graphs of the attacks in Cases 1 and 2. There is no sign of auricular fibrillation or ventricular standstill, but there is a sudden occurrence of ventricular fibrillation, which stops as suddenly as it begins.

Treatment with barium chloride by mouth, and adrenalin hydrochloride solution hypodermically, did not seem to be of any avail.

Analysis of Cardiac Phenomena.

Auricular Effects.—Auricular fibrillation was noted in Cases 1 and 2. This condition of the auricle bears no constant relationship to the incidence of attacks, so that it cannot in itself be the cause of them.

The auricular rate does not constantly vary before an attack and cannot be the precipitating factor. Also, it is the same during an attack as it was just before (Chart I.).

Ventricular Effects.—There is a continuous variation in the shape of the Q R S complexes throughout the series of cardiographs in Cases 1 and 2; there is also some variation in Case 3, when a right bundle block is present ab initio. In all the cases there is electrocardiographic evidence that tracts of inflammatory tissue are occurring in the course of the bundle of His. We suggest that the Stokes-Adams phenomena are dependent in some way on this. In Case 3 the inflammatory lesion has gone so far in the ventricle as to produce paroxysmal ventricular fibrillation.

Woolard [1] has worked out the innervation of the coronary vessels from an anatomical point of view. The physiological researches of Anrep and Segall [2] have demonstrated "the presence of vaso-constrictor fibres to the coronary blood-vessels in the vagi and of vaso-dilator fibres in the sympathetic nerves." Osler [3] comments that "the origin of the condition (Stokes-Adams syndrome) is probably vagal." It is apparent in all the cases that there is no sinus showing before an attack, for the auricular rate does not drop. The syndrome is not produced by vagal effects on the sino-auricular node. So far as we know, the auriculo-ventricular node "follows suit" to the sino-auricular node and is necessarily governed by the same influences. Hence it follows that the ventricular standstill is not due to a direct vagal effect on the auriculo-ventricular node. Assuming that the vaso-dilation of the skin found in Case 2 is evidence of sympathetic inhibition proportionate excess of vagal tone may be inferred. This should produce vaso-constriction of the coronary arteries. I suggest that the effect of vaso-constriction of the coronary arteries on the actively diseased myocardium is to produce ventricular asystole in Cases 1 and 2, and ventricular fibrillation in Case 3.

It is interesting to note that Anrep and Segall [2] note a difference in the properties of the vagal fibres controlling heart-rate and coronary flow respectively. "The vagal fibres controlling the heart-rate and those which regulate the coronary blood-vessels react differently to atropine. A small dose of atropine does not prevent the coronary effect, but it abolishes the effect on rate. A larger dose of atropine cuts out both effects."

Let us examine by considering the therapeutic action of the drugs what support is lent to the supposition that coronary constriction precipitates Stokes-Adams attacks. Atropine sulphate and adrenalin hydrochloride are both used to alleviate the attacks. Adrenalin only of the two has a direct action on the cardiac musculature in clinical doses, but both overcome an excess of vagal tone, atropine by paralysing the vagal ends and adrenalin by stimulating the sympathetic. It is logical to assume that it is just this common mechanism which is brought into play by the use of these drugs. Support is also lent to this idea by Case 1, where atropine was the more effective drug of the two. According to the work of Anrep and Segall, both these drugs should produce dilatation of the coronary arteries by their action on the autonomic nervous system—a conclusion which agrees with the speculation already advanced.

I would therefore put forward, as a hypothesis, that in a certain group of cases exhibiting the Stokes-Adams syndrome the underlying cause is an acute myocarditis and the precipitating cause is a vaso-constriction of the coronary arteries, depending on the action of the autonomic nervous system. The same factors may also be at work in those cases which exhibit occasional attacks over a period of years, if the inflammatory myocardial lesion exhibits acute exacerbations at various intervals. Such a case has not been described here. I have compared the electrocardiographs of these cases with that of Herapath,[4] published in THE LANCET. I cannot ascribe the incidence of the attacks in my cases to the presence of an ectopic irritable point in the ventricle such as Herapath describes.

I wish to thank Prof. O. K. Williamson, Dr. Watt, and Dr. I. Block for their courtesy in allowing me to use their cases and notes, and to Dr. L. R. Shore for his valuable criticism of the text.

Clinical and Laboratory Notes.

A NOTE ON THE QUIESCENCE OF IRRADIATED TUMOUR CELLS.

BY HELEN CHAMBERS, C.B.E., M.D. LOND.,
RESEARCH WORKER, MEDICAL RESEARCH COUNCIL;
AND
S. RUSS, D.SC. LOND.,
PROFESSOR OF PHYSICS IN THE UNIVERSITY OF LONDON.
(*From the Barnato Joel Laboratories, Middlesex Hospital.*)

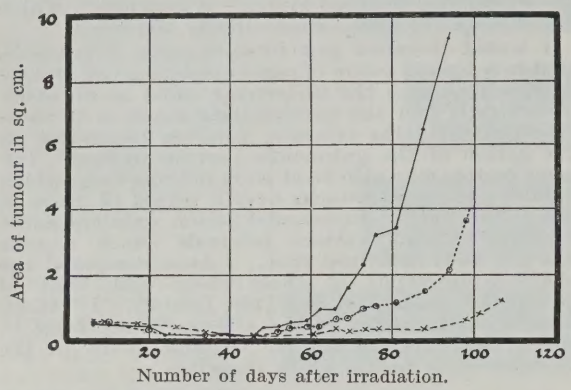
IN 1913 we published[1] the results of some experiments upon the ultimate fate of tumour cells (Jensen's rat sarcoma) after exposure to radium emanation.

When these cells were irradiated outside the body and then inoculated subcutaneously into rats, it was found that, after a "lethal dose," the irradiated cells were able to survive in the body for a period of about eight to ten days, after which very little trace of them could be found. When sub-lethal doses were given, the irradiated tumour cells grew, but at a reduced rate, and the onset of growth was often very much delayed. The extent of this delay in growth, a real quiescent period, may be gauged from the charts of three tumours shown in the figure, which are reproduced from the data given in the paper mentioned.

In the cases illustrated, 0·1 c.cm. of tumour cells was exposed to 0·275 millicuries for 30 minutes before being inoculated. It will be seen that the irradiated cells in one of the tumours showed practically no sign of active growth for something like 80 days, a considerable fraction of the life of a rat.

[1] Proc. Roy. Soc., Series B., 1913, lxxxvi.

Clinically, it must often be impossible to ensure that the cells of a tumour all receive the dose which is considered necessary to ensure a lethal effect, and the question naturally arises whether the cells which receive sublethal doses are likely to go through some similar period of quiescence only to renew their growth eventually. There is little doubt that, in a large proportion of the cases, the normal tissue reactions of the host play the important part of dealing effectively with damaged tumour cells, thus making



recurrences rarer than they would be, if one relied simply upon the direct effect of the rays upon the tumour cells. A striking parallel to this experiment has lately come to our notice, and seems worth recording.

In January of 1921 a woman of 73 was admitted to the wards of the Middlesex Hospital with a tumour in the right breast. This was removed by the late Mr. T. H. Kellock, and sent over to the laboratory under aseptic conditions. The tumour tissue was separated as far as possible from the normal tissues, and was then minced into a sterile petri dish and exposed to a beam of X rays. The dose given to the cells was calculated to be 1·5 times that given to the rat sarcoma cells for a lethal effect. A section of the tumour tissue showed it to be a colloid carcinoma.

After irradiation, 15 c.cm. of tumour tissue in all were inoculated intramuscularly in two abdominal pockets prepared at the time of the operation. The object in view was to try to induce a state of immunity in the patient by the absorption of irradiated tumour cells; the experimental basis of this was described in THE LANCET (1922, i., 212). Six and a half years after this operation was carried out the patient felt some very small nodules on the right side of the abdomen at the site of the inoculation. She said nothing about it till nearly six months later, when the nodules were plainly visible and evidently growing very slowly; nothing could be felt on the left side. There is hardly a doubt that these nodules represent growth of the tumour cells inoculated seven years ago, and which have been in a state of quiescence for all these years. The renewed activity of these cells appeared to coincide with the recurrence of nodules at the site of the original operation on the breast. The patient remains in good general health.

A NOTE ON TRAUMATIC RUPTURE OF THE SPLEEN.

BY J. DURLABH DHRUV, M.S. BOMBAY, F.R.C.S. ENG.,
SURGEON TO SIR J. J. HOSPITAL, BOMBAY.

IN tropical countries rupture of the spleen is fairly common. It will certainly be missed if the possibility of it is not considered in all cases of falls from a height, internal and external violence, and accidents by tram-cars, railway trains, motor-cars, &c. Even when injury is inflicted on parts other than the abdomen the spleen may be ruptured. In one case of fracture of the base of the skull rupture of the spleen was revealed at autopsy. In every case of injury to the skull, especially those due to falls from a great height, a careful examination of the abdomen is imperative. The high incidence of this accident in the tropics is perhaps due to the prevalence of certain tropical fevers of which the most important is malaria. I say "perhaps" because a small, apparently normal spleen with normal consistency has been found ruptured more than once. It may be conjectured that tropical spleens are certainly more vulnerable than those of dwellers in cold countries. I have not been able to show malarial changes in all the nine spleens I have removed in two years of Sir J. J. Hospital surgical practice.

Diagnosis.

Pulse.—This is no guide at all. When a small, quick, running pulse is present there is no question, but a good pulse of normal rate and volume may be consistent with a rupture of the spleen. Twice I have opened up the abdomen when a pulse of normal rate and volume was present and found rupture of the spleen. One should not wait for a "hæmorrhagic" pulse to diagnose rupture of the spleen.

Restlessness.—This is usually, though not invariably, present. In seven cases out of nine it was present to a varying degree. If the patient is admitted during the night and the house surgeon misses the diagnosis, the surgeon next morning on his round invariably obtains a history of restlessness during the night. The cases that have passed a restless night do not live as exploration comes too late.

Thirst.—In all my cases this symptom was constant, and I attach great value to it.

Dullness.—This physical sign is very much overrated. It is present in practically all cases, but its absence should not negative the diagnosis. Twice I have obtained a tympanitic note over the left iliac fossa, due to gas in the bowel and atony of the gut. Increasing and shifting dullness may be a valuable sign for some observers, but I must admit that I have not had much help from it.

Rigidity.—This sign is variable, depending more or less upon the amount of trauma suffered by the parietal peritoneum and not upon the quantity of extravasated blood present in its cavity. In most of my cases it was absent. In fact if rigidity is present I am sceptical of the diagnosis of splenic rupture. In one case of contusion of the abdominal wall where rigidity was very well marked I waited, and was not sorry for it.

Pain and Tenderness.—To me this is the most important and most infallible sign. It is surprising that so little stress has been laid on this point in surgical text-books. In almost all cases I have asked the patients: "*Kya hei?*" (What is the matter with you?) and they have uniformly answered "*Idhar hei*" (here it is). There is a definite tender spot about the left hypochondriac region. I have been much helped by this statement, and I always depend on it. Before operation I confirmed the diagnosis by putting a wide-mouthed needle into the peritoneal cavity. I have always found blood, although sometimes only after three punctures. I consider this procedure absolutely safe and surgical, considering the gravity of the situation.

The Technique of the Operation.

The abdomen is opened by a long left paramedian incision under light ether and local anæsthesia. The blood is mopped up with sponges and collected in a sterile bowl containing saline. Blood effused from a ruptured spleen, like extensive hæmothorax fluid, does not coagulate. Slight coagula may be found at the site of rupture, but the blood obtained from the pelvic cavity is all fluid. This blood is injected straight into the vein of the patient after it has been mixed with warm saline. The spleen is rotated on its axis medially and thus the hilum is brought nearer the surface of the wound, and the structures contained in the lienorenal ligament are ligatured in sections. The gastrosplenic ligament is easily separated, and a certain amount of traction has to be used in bringing the upper pole of the spleen into the wound. In the majority of cases removal is easy. Suturing the rent in the spleen is extremely difficult and risky, and should not be attempted, as it entails further hæmorrhage. Sometimes the two halves of the spleen come away separately. The commonest site of rupture is at the anterior border close to the hilum. In one case a vertical tear was found and three cases presented laceration of the lower pole below the hilum. I do not think it is possible to stop bleeding by suturing these areas, which are so friable that sutures will not hold. To my mind excision is the best treatment of an injured spleen which has caused severe bleeding, no matter how insignificant the injury.

The liver, stomach, and intestines should be carefully examined before the abdomen is closed. In one case a rent in the liver was missed and the abdomen had to be opened up again. Ligatures are left long and used as tractors, so that if there is oozing from the hilum fresh bleeding points can be easily secured. They are cut short as a last step before the abdomen is closed.

Rupture of the spleen associated with dilatation of the stomach is a very grave accident and usually fatal. The force that ruptures the spleen paralyses the stomach without any bruise or hæmorrhage on its walls. In one such case where the stomach ballooned out the patient died within 48 hours of the operation. Bruising of the gastro-splenic omentum is not so dangerous as dilatation of the stomach. In one patient I successfully ligated the bruised portion of the omentum in sections. The possibility of including the tail of the pancreas in the hilum is very much exaggerated as the fixation of the pancreas to the posterior abdominal parietes prevents it. As a rule one does not see the pancreas when the spleen is completely brought out into the wound.

Results and Conclusions.

The results on the whole have been very encouraging, but early diagnosis would certainly improve them. Five out of my nine cases recovered, the causes of death in the other four cases being dilatation of stomach, fracture of the base of the skull, delay before operation (the patient had a restless night as the house surgeon did not recognise the situation), and injury to the liver, which was not noticed.

A CASE OF ACTINOMYCOSIS OF THE APPENDIX.

BY FRANCES M. G. SINCLAIR, M.B. ABERD.

With a Note on Laboratory Findings by

S. C. DYKE, D.M. OXF., M.R.C.P. LOND.

ACTINOMYCOSIS of the appendix is comparatively rare, and recovery from it is even rarer. The following case is therefore of interest.

The patient, a single woman aged 65, was seen on the morning of July 18th, 1927, when she showed all the signs of acute appendicitis. She had had some pain the day before, but had been well enough to attend church in the evening. At operation on the afternoon of the 18th a perforated appendix, well shut off by omentum, was found; this was removed and the wound closed with one tube for drainage.

The patient did well for two weeks, when the temperature rose a little and the left leg became œdematous and slightly painful. The pyrexia continued and two days later a swelling could be felt in Douglas's pouch. She was seen by Mr. B. T. Rose, who opened the abdomen in the mid-line and evacuated a large pelvic abscess; the wound was partially closed, a large pack left in to control hæmorrhage, and a drainage-tube inserted. In the course of the next few days most of the wound broke down, leaving the intestines exposed and pus poured out in increasing volume. Ten days afterwards the liver became enlarged and tender, jaundice developed, and the fæces became clay-coloured; two days later there was a rigor with a temperature of 104° F.

On the 20th the patient was seen by Dr. S. C. Dyke, consulting pathologist to the Walsall General Hospital, who took blood for cultural and other examinations and specimens of the pus. Dr. Dyke reported that smears of the pus showed a streptothrix of the actinomycotic type, and advised treatment by large doses of potassium iodide and a vaccine. The administration of potassium iodide was at once commenced in doses of grs. 20 three times daily, and a stock vaccine of the actinomycotic streptothrix was obtained from Messrs. Parke, Davis and Co.

For the following five weeks the patient ran a high swinging temperature with occasional rigors and pus continued to pour from the wound. The dose of potassium iodide was gradually raised until by the middle of September the patient was taking grs. 35 three times daily. About this time the wound commenced to close in, and by the second week in October had healed sufficiently for the patient to be removed from the nursing home to her own house. At this stage there was a long sinus running down into the left side of the pelvis from which pus was still discharging profusely; the original appendicectomy wound had by this time healed completely. The liver remained enlarged and tender, but the jaundice had disappeared; the œdema had subsided in the left leg, but had reappeared in the right; the mental condition had deteriorated and the patient was depressed, suffered from failure of memory, and from time to time from delusions.

The wound continued to close, and the discharge to become less; the temperature settled, but the patient developed intermittent attacks of pain in the right hypochondrium with dullness and tubular breathing at the right base accompanied by some dry cough. She became more and more listless and apathetic, took no interest in anyone or anything, and completely lost her memory for recent events. Early in November it was decided on account of the mental state to discontinue the potassium iodide, and at the request of the relatives the vaccine was also dropped. The mental condition at once began to improve, and by the end of the month she had regained sufficient interest in life to start reading the newspaper again; the improvement was maintained, and by January the patient was able to get out of bed. By March the general condition was good, but the patient still had a discharging sinus requiring dressing at least twice daily. Another short course of the vaccine was given, and the potassium iodide was restarted in doses of grs. 10 three times daily, but the patient refused to go on taking the drug as it made her so depressed.

The healing of the sinus continued, and it now discharges only an occasional bead of pus. The abdomen now presents no abnormalities other than some herniation through the scar of the second operation, which is controlled by a belt; the lungs are clear and the patient is leading the same sort of life as before the operation.

Note on Laboratory Findings by DR. DYKE.

Blood culture taken on July 20th gave no growth after 72 hours' incubation. The blood gave a negative direct van den Bergh reaction, and a slight positive indirect. Urine showed no bile salts, pigment, or urobilin. Films of the pus from the second operation wound showed numerous coliform bacilli and a few streptothricial threads. On the strength of this finding a larger supply of pus was asked for, and several cubic centimetres were forwarded by Dr. Sinclair on the following day. This pus showed numerous filaments and some dense clumps of streptothrix. The threads were Gram-positive, but failed to take the fuchsin when stained by the Ziehl-Neelsen method. Cultures were made on ordinary nutrient agar, on glucose and glycerine agar, and into plain and glucose broth, and were incubated both aerobically and anaerobically; but no growth of the streptothrix could be obtained. Pus was inoculated subcutaneously into the back of one mouse and intraperitoneally into a second one; both animals survived until killed six weeks later, when neither showed any sign of disease.

Walsall.

THE WOLVERHAMPTON HOSPITALS.—The Counsellors of State, on behalf of the King, have given authority to the Wolverhampton amalgamated hospitals to be called "The Royal Hospital." The institutions recently amalgamated are the Wolverhampton and Staffordshire Hospital, the Wolverhampton and District Hospital for Women, and the District Nursing Association and Maternity Home.

EDINBURGH ROYAL INFIRMARY.—The annual report of this institution shows that during the financial year 18,779 patients were admitted, which with 901 patients in the infirmary at its opening makes a total of 19,680 treated—an increase of 967 over the previous year. Of the cases admitted Edinburgh furnished 8815 and the country 9964. Out-patients to the number of 62,085 (most of whom attended several times) received medical and surgical aid. At the Convalescent House the total number of patients admitted was 1612. The report states that on August 6th the institution will have completed 200 years of beneficent work.

At a recent meeting of the managers the retirement of Dr. William Fordyce from the charge of a gynæcological ward was intimated. The managers, in recognition of his valuable work in the infirmary, unanimously invited his acceptance of the position of consulting gynæcologist. Dr. Fordyce has acted as a member of the honorary staff for 22 years. He was appointed assistant gynæcologist in 1906 and gynæcologist in 1921. Warm appreciation of his loyal services to the institution was recorded.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

A PATHOLOGICAL meeting of this Section was held on Jan. 2nd, Prof. GEORGE GASK presiding.

Sir LENTHAL CHEATLE gave a demonstration of transillumination as an aid to the diagnosis of breast diseases, a method which he was first made aware of by having it demonstrated to him by Dr. Max Cutler, in New York. (See THE LANCET, 1928, i., 38.) The method was very simple, and he regarded it as of distinct value.

Sir LENTHAL CHEATLE also made a communication on

Sterilisation of Surgical Drums.

He criticised the drum most commonly in use at the large hospitals, stigmatising it as one of the most septic things imaginable. He did not think any bacteriologist would trust a result which was founded on such so-called sterilisation as was applied in a typical drum shown on the screen. Steam, he said, was used under a pressure of two atmospheres, and certainly sterilisation of everything in it was attained; but air also had to be admitted, and, though cotton-wool was used, the portals of entry for the air were so large, and the passage of steam took place at such a great pace, that sterilisation in the end was not by any means complete. Any dressings exposed to this process, however thoroughly sterilised at first, were rendered septic again by the passage of air and its contents. He understood that the makers had never thought of testing the efficacy of the machine bacteriologically. His purpose in making the communication was to warn surgeons as to the possible fallacy of claims made for drums. Sometimes the drums were put into the sterilising apparatus open, sometimes closed, but even when closed the air openings were not closed; and air entering the machine for drying purposes was the vehicle for reinfection. The holes, moreover, were large enough to admit humming birds, humble bees, and grasshoppers; even maggots had been discovered in drums. The speaker had been experimenting with the object of evolving a more efficient sterilising drum, and his final result, which he demonstrated, was a tin having two grooves. Cotton-wool put in the two grooves and the lid on top kept the contents sterile until they were required for use. The difficulty was how to get steam into the drum to carry out the sterilisation; this difficulty was obviated by evacuating the steam and the air three times during the process, the sterilisation occupying two hours. When this method was employed efficiently the dressings, aprons, masks came out sterile and dry. With the apparatus now in general use he did not think the results were any better than after the ordinary wash.

The CHAIRMAN said the communication caused him to feel a little disturbed, because when, as a student, he was attending the bacteriology class, one of the duties was to examine the drums with the big holes, as described, and students were taught to believe that what came out of them was sterile.

Mr. DUNCAN FITZWILLIAMS said that if one bought from a store a roll of ordinary gauze, and removed the first three layers, the remainder of the roll would be found to have come from the manufacturer sterile. He referred to a war experience in Roumania in the matter of improvisation, and spoke of Dr. Cathcart's use of sterile sawdust as a cheap dressing, the centre pith of the wood being torn out and dropped into a pit, always being found strictly sterile.

Mr. FITZWILLIAMS showed a series of patients on whom he had carried out, at various dates,

Partial Removal of Breast for Early Carcinoma.

He said that probably the breast was the only site in the body in which a truly radical operation was carried out—i.e., in which the growth, the lymph field, and the whole area surrounding it. In cancer of the tongue the operator was not nearly so radical, being content with removing a portion of the tongue and the neck glands. In the rectum, too, though this was a danger area, the operation usually done was less sweeping than that in the breast. For breast carcinoma Halstead had recommended that the glands above the clavicle should be removed, because they were in the lymph field. Many surgeons, however, now left them untouched. The speaker suggested to his colleagues that in early cases of breast carcinoma much more could safely be left behind than was usual. The earliest case on which he had operated in this partial way was seen by him 23 years ago, and the patient was still alive; he had had 20 cases with a survival of one and a half to two years so far; while that evening he showed patients who were operated upon five, three, and two years ago. The theory on which he worked was as follows. Cancer was recognised to be, when it started, a local disease—when it was the size of a millet seed. At that stage, he contended, it was successfully removable by a purely local operation; it was so small that it was related to only the finest radicals and lymphatics. If left longer it ate into larger lymphatics, and so glands in the neighbourhood were involved. The difficulty lay in knowing just when it was so strictly local. His own working definition of "early carcinoma" was carcinoma without a single distinguishing malignant attribute. Years ago the teachers at Johns Hopkins school said that the presence of one malignant characteristic in diseases of the breast reduced the surgeon's chance of success by 25 per cent.; while if there were two malignant characteristics the chance was reduced by a further 25 per cent. That Mr. Fitzwilliams held to be true. When a tiny nodule of the breast was discovered the examiner had no right to tell the woman it was "nothing"; it ought to be removed forthwith. He remembered one case in which he could not satisfy himself that there was a lump; but in six months the woman came back with a flaring carcinoma. In a very early case sections would show several doubtful slides, and only one which could be called carcinomatous. He contended that a very early case of carcinoma of the breast could be cured by merely doing this partial operation. He was sure many cancer cells were destroyed by natural processes. The first gland to be infected would be blocked, and so very little or no lymph would pass through; hence this gland, at this stage, would not infect other glands. Until one knew a gland was infected there was no reason why it should be removed. In 30 cases he had seen no reason to regret having done only the partial operation.

When, at a distinctly later stage, infected lymph was flowing elsewhere and nodules were present at different sites, however radical the operation, it would be of little avail. In the smaller operation one did not find secondary growths all round the wound, as in the case of the larger surgical procedures.

The CHAIRMAN said a partial operation of such limited extent was contrary to surgical teaching, though it was probably supported by a partial truth. It was, however, preached by his chiefs a long time ago. His own immediate chief sometimes did only a small operation on the breast, occasionally taking away glands also, but sometimes not. And other surgeons, whose opinions he valued, had also done the small operation and shown good results. His, the speaker's, own trouble was in knowing when there was present only a small local growth. In some of the cases of carcinoma of the breast which he had regarded as very early, he found metastatic growths occurring quickly afterwards. If a growth could be caught before dissemination and destroyed by means of the cautery, or radium, or other method, a cure would probably ensue. But how was one to know

that a case had only reached that stage? Mr. Fitzwilliams instanced in comparison tongue cancer, but in that organ the results were bad.

Sir LENTHAL CHEATLE said he agreed that if a case were met with early enough, local excision would probably suffice. But there must be malignant disease in the terminal ducts and acini before any of the cells got out. His own view was that to adopt the method of local removal was a retrograde step. He remembered several cases in his career, and in the career of other surgeons, in which the axillary glands were enormous and yet it was very difficult to detect even a small primary nodule in the breast. In a series of cases he examined the vessels and tissues round the axillary vein before doing the complete operation, and in only one was that area free from carcinoma.

Dr. D. F. CAPELL asked whether, as it was often impossible to find changes in the breast apart from the local area, there was not a risk of further development of carcinoma from some of these other foci. He had examined a series of such cases and had found changes bordering on cancer in multiple foci. When only a small part of the breast was removed, was not one leaving behind an area which might later become malignant?

Mr. FITZWILLIAMS, in reply, said the points raised concerned a wider area than he had opened up. The idea of merely local removal was not new. The crux of the matter was, if it was felt that removal of half or three-fourths of the tongue sufficed for cancer of that body, why should not a like local removal be enough in very early breast carcinoma? In the early cases he was speaking of there were no enlarged glands in the axilla, nor was there a single malignant characteristic present. If there were such signs a larger operation must, of course, be done. In precancerous leucoplakia of the tongue it was not the practice to remove the tongue.

Prof. C. A. PANNETT submitted a communication on

The Use of the Cautery in Operations on the Stomach.

He explained that he was not referring to the cauterising of ulcers. The problem was the following. Often a patient with gastric disease was thin, emaciated, half-starved, and so was not in a fit condition to undergo a severe abdominal operation. Hence the conservation of every possible drop of blood became a prime consideration. The generally employed methods of performing gastrectomy did not always meet the situation in this respect. It was easy to tie off the lesser omentum and the greater omentum and to proceed, bloodlessly, to a stage at which the actual growth or ulcerous area must be excised. But in the case of a large gastrectomy for high gastric ulcer or carcinoma he had frequently found it impossible to use the ordinary hæmostatic clamps to control hæmorrhages while cutting the viscus across. He had been using a simple procedure for working without hæmostatic clamps. In some clinics, faced with the same situation, the Paquelin cautery had been used, but this was a clumsy method of dividing the stump, and it burned a wide area of the viscus and led to a wide cicatricial band. He had never seen anybody divide viscera with the ordinary Paquelin cautery. When using the cautery for dividing the stomach, two things were necessary. First, one must minimise the amount of heat required, which was done by temporarily controlling the circulation, which would otherwise act as a cooling stream. Secondly, the clamp used must be massive enough to conduct away the heat, so that the tissue around the clamp was not burned. He used two forceps, one of them fenestrated. He described the details of his procedure by means of illustrations on the epidiascope. The adoption of this procedure, he said, had enabled him to operate on people on whom he would not otherwise have ventured. One patient who dealt with died subsequently from a pulmonary trouble and there was found to be no difference in the operation site as compared with the ordinary hæmostatic cautery suture.

Specimens and Cases.

Mr. C. P. G. WAKELEY showed two specimens. The first was one of cavernous angioma of the brain, from a woman aged 25 who came to hospital because of the weakness of the left arm and left leg. Beyond some excitement, nothing pointed to a cerebral lesion. Post mortem, œdema was seen round the angioma in the brain, and it had led to secondary hydrocephalus. The other case was a meningeal myxoma. The man, aged 48, had had fits and some paralysis of the leg. X rays were of great help in locating the tumour. An osteoplastic flap was turned down, and as soon as the dura mater was exposed the growth bulged into the wound, and on incising the dura the tumour spontaneously presented. Shortly after the operation some paralysis of the leg occurred, but that soon cleared up, and the patient got quite well.

Prof. PANNETT praised the surgery carried out in this case.

Mr. GWYNNE WILLIAMS showed a patient on whom he had carried out partial exclusion of the thoracic aorta for the cure of pain. The man had had aneurysm of the abdominal aorta five years, and came to him for the relief of his pain. Mr. Williams reduced the pulse in the femoral in the groin by pressure, and pain had now practically ceased. He could not put a wire in as the aneurysm was too extensive.

Other cases were also shown.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

A MEETING of this Section was held on Jan. 8th with Dr. H. H. DALE in the chair. An informal discussion on the treatment of

ESTABLISHED DIABETIC COMA

was opened by Prof. E. C. DODDS, who pointed out that the subject allotted limited the discussion to methods of bringing a comatose patient back to consciousness. At the Middlesex Hospital they relied for the insulin dosage on blood-sugar estimations. The blood-sugar estimation took about 15 minutes and then the first dose of insulin was given, usually about 100 units; thereafter the blood-sugar was watched and the dosage adjusted accordingly until the patient recovered. It was possible to work with urine-sugar estimations up to a certain point—about the time when the patient began to lose his air-hunger—but thereafter grave risk was run if blood-sugar estimations were not made. He disagreed with those who regarded it as waste of time to administer glucose; apart from the benefit to metabolism, glucose acted as a barrier against hypoglycæmia. The alkali reserve was worth determining, for it revealed more than did the blood-sugar estimation or the simple tests for acetone bodies in the urine. The majority of patients treated in this way recovered, but a certain number died. For these deaths three reasons had been put forward: (1) Inability to control the diabetes so that hyperglycæmia and ketosis continued. This occurred chiefly in septic cases and therefore did not come into the present discussion. (2) Kidney damage, leading to retention of urea and a uræmic coma very like diabetic coma. Investigation of a series of cases had shown, however, that high urea and non-protein nitrogen content in the blood was not unusual in diabetic patients, and that it occurred in those who recovered from coma as much as in those who died. (3) Failure of the circulatory system. Two patients at the Middlesex who had died in coma had had low blood pressure and had appeared to die of circulatory failure. The total acetone bodies in their bloods had been below normal, about 3·5 mg. per 100 c.cm.; in one case the blood had been taken just as the patient died. The blood pressure was of great prognostic importance. In these two cases the subcutaneous administration of ephetonin and pituitrin had failed to save the patients' lives.

An Instructive Case.

Dr. GEORGE GRAHAM said that all his patients had either recovered or had first been treated very late. Four weeks ago, however, he had had a case which might be instructive.

The patient was a boy of 16 who had been doing well on diet and insulin for six years and had entered for an examination. He had felt ill and done his papers badly, and had gone to bed without either food or insulin. At 12.30 A.M. he had vomited. At 3.30 A.M., when his mother had seen him, he had been obviously ill, and she had supposed him to be suffering from hypoglycæmia and had given him adrenalin and sugar. When the doctor had seen him at 6.30 A.M. he had been dazed and had complained of pain in the right side of the abdomen, for which morphia had been given. He had then had more sugar and travelled 30 miles to hospital by car. On arrival he had been very cold with a pulse-rate of 120, a blood-sugar of over 700 mg., and a white blood cell count of 32,000; 100 units of insulin had then been given. The possibility of a gangrenous appendix had led to a laparotomy—the first error in treatment, for nothing abnormal had been found. At 4 P.M. the blood-sugar had again been over 700 mg. and 50 g. of dextrose and 150 units of insulin had been given. He had smelt strongly of acetone, and the blood had flowed sluggishly when withdrawn for testing. He had therefore been ordered saline infused by gravity, the dextrose and insulin doses being continued. At 10 A.M. the next morning a blood count had shown 5,800,000 red cells, 6000 white cells, and a hæmoglobin percentage of 108. The blood-sugar had dropped to 240 mg. At 11.30 he had received another 100 units of insulin by mistake, and the next 24 hours had been occupied in keeping him out of hypoglycæmia by the administration of sugar per rectum and per os. At 11 P.M. the blood-sugar had risen to 170 mg. but at 3 A.M. the patient had become pale and rigid, being restored to normal by the administration of adrenalin and dextrose. At 8 o'clock next morning the blood-sugar had been 40 mg. and adrenalin had been repeated, followed by 10 units of pituitrin and dextrose intravenously. Next morning he had been better, with a blood-sugar of 370 mg.

The urine of this patient had contained granular casts and pus cells but no red cells, and not until the sixth day had acetone bodies appeared in it; then the reaction had been very strong until, on the fourteenth day, there had again been no acetone in the urine. The boy had gone into coma because he had had something wrong with his kidneys and they had been unable to excrete acetone bodies. Treatment of diabetic coma must be by the administration of plenty of insulin and plenty of sugar; it was a mistake to give insulin without waiting for the blood-sugar estimation. Further, fluid should be given intravenously; one patient who had died of circulatory failure had had a hæmoglobin percentage of 140 per cent. These patients died from a condition akin to surgical shock; they could not keep fluid in their blood. Therefore fluid must be given them, if necessary under pressure. There was often some vein spasm which prevented the entrance of fluid under gravity.

The Administration of Glucose and Alkalis.

Dr. R. D. LAWRENCE said that he had not had many cases of diabetic coma, as the pre-comatose patient usually recovered with insulin and glucose. He agreed that the patient was dehydrated, as judged by the tension of the eye, and should at once receive large quantities of intravenous saline. With this, where the pulse was collapsed, should be given a drop or two of adrenalin. Difficulty in getting the fluid in could be overcome by the use of a blood transfusion syringe. Strophanthin might be given for the heart, but the effect of adrenalin alone was often miraculous. It lasted for 20 to 40 minutes. The whole problem was one of circulatory depression, and the failure of the kidney to excrete acetone bodies had nothing to do with the severe condition of the patient. He did not agree, however, that glucose should always be given; its administration was unnecessary and unphysiological. When the blood-sugar could be watched sugar should not be given at the outset, but for the patient outside hospital it was essential from the first, as it was impossible to tell how quickly a patient would respond to the insulin. Improvement usually coincided with lowering of the blood-sugar, but the patient might just as well recover with a high blood-sugar. The old overdosage with alkalis was now discarded, but it was wise to give small doses of sodium bicarbonate in the early stages. He detailed a case illustrating the very prolonged effect insulin might have once it got going. In this patient it had required large doses of insulin to get the blood-sugar down in the first 12 hours, and it would never have come down if glucose had been given as well.

Prof. HUGH MACLEAN said that everybody was agreed on the general treatment of these cases and that large doses of insulin should be given. At his hospital it was the custom to give 50 units before the blood estimation and thereafter to regulate the dose by the blood-sugar. He agreed that when the blood-sugar could be watched it was unnecessary and unphysiological to give large amounts of glucose. There was no doubt of the efficacy of cardiac stimulation, and camphor might have a marked effect in some cases. It must be remembered that a high blood-sugar in itself did no harm so long as there was no acidosis, and that it did not really matter whether the blood-sugar were lowered or not. The principles of treatment must be directed towards supplying large amounts of insulin and moderate amounts of blood-sugar. It was possible for a patient to be suffering simultaneously from diabetic coma and insulin hypoglycæmia, and a fall in blood-sugar did not necessarily indicate the passing of coma. A patient with a blood-sugar of 0·01 or 0·02 might pass huge quantities of ketone bodies in his urine and be in coma. For the general practitioner who could not obtain blood-sugar estimations the problem might be a very difficult one, and under these circumstances plenty of glucose should be given, after the initial dose of insulin. The effect of diabetic coma on the circulatory system was very severe, and grave additional risks were run if the blood-sugar were allowed to get so low that insulin hypoglycæmia might supervene, for this in itself was very detrimental to the cardiac mechanism. In angina patients the brief periods of hypoglycæmia following administration of insulin might precipitate an anginoid attack and cause death. It was bad to give large amounts of bicarbonate; it had been shown that the administration of sugar after a period of fasting would fail to stop the ketonuria if a dose of bicarbonate were given previously. Small doses, however, were indicated because of the low alkali reserve and the depletion of the alkalis of the body.

Dr. O. F. LEYTON said that he had not been convinced that sugar was harmful. Sugar could not dehydrate the patient if plenty of water were given with it. In his experience patients with a low renal threshold might develop diabetes mellitus, and even if this were not admitted, the renal threshold was not constant and might fall very low indeed in diabetic coma and hypoglycæmia. It was therefore dangerous to conclude that because there was sugar in the urine more insulin might be given.

The Time Factor and the Age Factor.

Dr. P. J. CAMMIDGE said that error was bound to occur if it were assumed that all diabetic coma was one and the same thing. The treatment depended greatly on the time that coma had existed and on the age of the patient. Diabetic coma had first been ascribed to acidosis, then to changes in the hydrogen ion concentration of the blood, and now it was believed to be due to changes in the osmotic pressure in the cells and between the cells and the plasma: depletion of the fixed bases from the nerve cells led to unconsciousness, and from the heart to weakness, fall of blood pressure, &c. In the early stages patients would recover rapidly if the acetone and other bodies which were combined with the fixed bases could be removed. Fairly large doses of insulin intravenously were all that would be required. Other patients, who had been unconscious for some time, would not be affected by any amount of insulin. The patient who recovered easily was usually young. The elder

patient as a rule needed sugar as well as insulin, and even then the rate of oxidation of the ketone bodies could not always be speeded up beyond a certain limit. The only way then was to give alkalies intravenously in small amounts, along with the insulin and glucose.

Dr. W. W. PAYNE emphasised the fallacy of testing the urine alone. He quoted a case where the urine had shown no sugar or acetone bodies and the blood-sugar had been 0·5, but the patient had died in uræmic coma with a blood-urea of 250 mg. Another patient had been in coma for two days; on the first day he had had acetone bodies in the urine but they had been absent on the second day, although there was no lack of them in the system.

The Significance of Chlorides and Phosphates.

Dr. C. G. WOLF mentioned the work of Prof. L. Blum and his colleagues at Strassburg on the depletion of chlorides in the body in diabetic coma. They thought that part of this condition was due to the very low chloride content of the body. The addition of sodium chloride to the insulin seemed to have a good effect, one that was not produced by any other sodium salt.

Dr. PHILIP HAMILL pointed out that it was dangerous to give repeated doses of morphia subcutaneously for cholera because the drug might remain in the skin while the circulation was poor and be taken up again when the administration of saline had improved the state of the blood. He suggested that the same fate might befall subcutaneous insulin when the patient was dehydrated.

Dr. F. B. BYROM referred to his work on the phosphate-content of the blood. In three fatal cases of diabetic coma he had found the phosphate-content extremely high, a condition only found in uræmia. This suggested that renal drainage played a large part in patients with diabetic coma who arrived late at hospital.

Dr. G. C. LINDER described a patient with diabetic coma who had come into hospital with 400 mg. of blood-sugar and a carbon dioxide concentration of 8 volumes per cent. in the whole blood. He had been given 10 g. of bicarbonate intravenously, which had only raised the carbon dioxide to 17 volumes per cent., although the hyperpnœa had disappeared and the patient improved. Another 15 g. of bicarbonate had brought the carbon dioxide content to 39 volumes per cent. without any evidence of overdosage. This showed that large doses of alkali could be given, provided their effects were followed by determinations of the carbon dioxide in the blood. The patient had been under a tremendous handicap owing to his very low alkali reserve.

The CHAIRMAN said that the suggestion made by Dr. Hamill had occurred to him, and he thought it might be wise to begin by administering a small dose of insulin intravenously rather than a large one subcutaneously. If a rabbit were given insulin hypodermically it would suffer from hypoglycæmia in half an hour. It could be brought round from this state, but its troubles were not then over, for in another hour it would be down again. It had to be treated repeatedly for several hours. In cholera hypertonic saline had been found preferable to normal saline, and it might also be better for the diabetic.

Dr. CAMMIDGE pointed out that Joslin in pre-insulin days had strongly favoured the administration of sodium chloride to patients with acidosis, because it kept the ketone bodies locked up in the tissues, so preventing them from circulating and doing damage.

Dr. GRAHAM, replying for himself and Prof. Dodds, said that he had simply given saline because the blood was sticky. Prof. Dodds agreed that the saline should be hypertonic and thought that it would be wrong to leave out sugar as a general rule because of the danger of passing too quickly from hyper- to hypoglycæmia.

Dr. LAWRENCE remarked that insulin did not act particularly in the blood, and that its action was usually protracted. The continued effect of large doses could easily be explained without assuming a delay in the skin. He had tried intravenous injection in a case where subcutaneous administration had failed, but without effect.

Dr. CAMMIDGE said he always began with a small intravenous dose of insulin, taking some blood away for testing at the same time, and went on giving small doses until a definite effect was obtained. It was possible to carry out sugar estimations at the bedside by the picric acid method, and to obtain comparable results.

WAR SECTION.

AT a meeting of this Section on Dec. 10th, with Lieut.-General Sir MATTHEW FELL, the President, in the chair, a paper on

Some Common Problems in Naval Hygiene

was read by Surg.-Commander P. M. RIVAZ. From what he said it appears that ventilation by punkah-louvres, which direct the entering air to the point where it is desired, are highly successful in the Navy, and exhaustion of air is serviceable in galleys, lavatories, and engine-rooms, though not in cabins or mess-decks. Constant vigilance by ventilation committees is needed to keep the supply of air working well. Fans must be rested, in cabins and mess-decks by day, in offices by night. Current opinion is in favour of more table fans. Clothing must be very light in the tropics; officers are apt to be too much clothed. If stokers working on coal fires wear too little they get scorched; if too much they get heat-stroke. Deficiency diseases and diets suitable for the tropics are under investigation. It is hardly possible, Surg.-Commander Rivaz considers, to compare the prevalence of tuberculosis in the Services with its prevalence in civil life, where notification is still very uncertain. Every man under 36 in the Navy is weighed once a quarter, and all chests are examined every six months, but the early doubtful case is still a difficulty.

In the discussion following this paper Major-General H. P. W. BARROW said that ventilation and the reduction of overcrowding had been found of great importance in relation to troop transport by sea. With enlarged cubic space, better spacing of hammocks, hospital admissions in troopships had gone down from 631 in 1914 to 277 in 1926. Experiments on vitamins and diet were to be undertaken in the East and much was hoped from them, also from the forthcoming report of the Joint Committee on Tuberculosis.—Fleet-Surgeon W. E. HOME said that overcrowding had been defined by Sir Thomas Fraser as a function of the number of persons occupying a space and the efficiency of the ventilation of that space. He (the speaker) had seen men with only 100 cubic feet of space develop illness from overcrowding in a month.

PATHOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND.

A MEETING of this Society was held at St. Bartholomew's Hospital, London, on Jan. 4th and 5th, with Prof. E. H. KETTLE in the chair.

J. W. McNee (London) discussed the pathological classification of chronic splenomegalies met with in Britain and drew special attention to the common type starting with hæmorrhage round the ellipsoids with subsequent fibrosis and siderosis, the actual gross enlargement being due to venous obstruction. He regarded true Banti's disease as very rare.—J. M. Ross (London) exhibited a specimen of the rare form of splenic enlargement due to overgrowth of the Malpighian bodies (Foix and Roemmele type).—J. S. Young (Leeds) found that salts injected into the pleura stimulated hyperplasia of the alveolar epithelium in proportion to the valency of the kation. The cells are refractory to a second dose.—I. Berenblum (Leeds) obtained a few epithelial tumours in mice by repeatedly freezing the skin with CO_2 snow. Freezing did not increase the carcinogenic efficacy of tar which is actually diminished by mustard gas.—

H. J. B. Fry (London) discussed the incidence of positive Wassermann reactions in patients with malignant disease; those with buccal cancer gave a much higher proportion of positives than the rest, but on the whole syphilis appeared to have little relation to malignancy.—J. R. Perdrau (London) discussed the acute disseminated encephalomyelitis associated with vaccinia and other infections; he thought that the perivascular demyelination was probably due to a toxin. An example of the condition following measles was described by J. G. Greenfield (London).—D. F. Cappell (Glasgow) had found that sugar of iron injected intravenously was quickly taken up by endothelium, after a few days liberated into the blood in a recognisable form and thence taken up again by the histiocytes of connective tissue, lymph glands, kidney, and liver in which it remained (in mice) for many months.—R. D. Passey, G. M. Bonser, and M. J. Stewart (Leeds) from a study of human and animal melanomata concluded that the melanin was made by the tumour cells but that the great majority of cells in which it was found were large mononuclear phagocytes.—C. Price-Jones (London) has measured 500 red blood corpuscles in each of 100 normal adults; the smallest mean diameter was 66μ, the largest 7·49, the average 7·198. The excess of large cells in pernicious anæmia could be calculated from these standards.—F. Parkes Weber (London) described a case of generalised osteosclerosis with severe anæmia.—W. W. C. Topley, M. Greenwood, J. Wilson, and E. Newbold (London) showed how the efficacy of experimental vaccinations could be elegantly tested by exposing the inoculated animals with their controls to an epidemic established in a mouse colony, and gave some of the results they had obtained with *Bacillus aertrycke*.—F. C. Happold (Leeds) described his observations on the group relationships of Salmonella precipitinogens and the influence of cultural variations.—A. Felix and M. Rhodes (London) and R. M. Pitt (London) discussed various aspects of bacterial dissociation, and P. B. White (London) gave an account of some pitfalls in the agglutination of rough strains and showed a differential test for smooth and rough bacilli.—A. S. Strachan (Johannesburg) compared his post-mortem experiences in South Africa and Glasgow. Atheromatosis is very common in whites and natives, and calcification of the mitral value is the rule over middle age; high altitude, excessive exercise, and much sunlight might be causes. Arteriosclerosis is not more frequent than in Britain. Natives show a great excess of primary carcinoma of liver, not associated with bilharzia; tuberculosis of heart, pericardium, and spleen are relatively common, also hæmochromatosis. Lymphatic tubercle often resembles lymphadenoma.—A. Fleming (London) concluded that the bactericidal power of blood on pneumococci was due to the combined action of leucocytes and serum, but that phagocytosis was not a necessary part of the process.—G. H. Eagles and D. McClean (London) described the cultivation of vaccinia virus in tissue cultures of chicken embryo.—C. H. Andrewes (London) found that immune vaccinia serum had no effect on the lesion at the site of inoculation but prevented subsequent generalisation. Virus fixed to tissue cells was unaffected by serum.—J. B. Buxton (Cambridge) had reproduced caseous lymphadenitis in sheep by inoculation or feeding with the Preisz-Nocard bacillus.—R. E. Glover (Cambridge) confirmed the finding that contagious pustular dermatitis of sheep is due to a virus, filtrable with some difficulty, which withstands drying well. No inclusive bodies were found in the lesions. The disease occurs mostly in fat lambs in the summer and affects no other animals except goats—T. Dalling (London) showed that vaccination of ewes with formalised bacilli of the special type of *Bacillus welchii* prevented lamb dysentery as well as toxin-antitoxin mixtures; resistance is transferred from ewe to lamb through the colostrum.—S. Ellingworth, J. W. McLeod, and J. Gordon (Leeds) gave an account of the oxidation of dyes of the paraphenylenediamine series by various bacteria and pointed out the value of the production of Wurster's violet in diagnosis.—J. H. Dible and C. Weatherall (Cardiff) found that enterococci nearly always fermented æsculin; they give hæmolysis only on blood-agar, not in broth.—R. Ellis and C. H. Whittle (Cambridge) described an apparent epidemic of pneumonia in a country village.—D. Nabarro (London) urged that the frequent occurrence of real bacillary dysentery (Sonne, Flexner, parashiga, and Shiga) in Britain, especially in children, should be more widely recognised.—V. D. Allison and T. H. Ayling (London) described a new tellurite-copper-sulphate medium for the isolation of diphtheria bacilli.—H. W. Crowe (London) claimed that certain streptococci could be shown to have a selective affinity for bone.—Among the exhibits were: M. J. Stewart and A. C. Haddow (Leeds): "peculiar bodies" of pulmonary asbestosis obtained by lung puncture. H. J. B. Fry (London): three cases of chordoma. D. Nabarro (London): congenital syphilis with enlarged thymus and lymphoid hypertrophy. D. F. Cappell (Glasgow): myeloma (*a*) plasma celled, (*b*) type with tumour nodules and visceral lesions. M. J. Stewart and S. J. Hartfall (Leeds): chronic peptic ulcer at lower end of œsophagus. G. S. Williamson, I. H. Pearse, and R. McCarrison (London): experimental and spontaneous lymphadenoid goitre.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this Society held on Jan. 3rd, with Mr. GEOFFREY BATE, the President, in the chair, a paper on

Chronic Appendicitis and Conditions which Simulate It

was read by Mr. H. N. FLETCHER. In describing the various forms of pathological appendix seen at operation he referred to a not very common variety usually seen in children, in which there was very marked hypertrophy of the adenoid tissue of the mucosa and large fleshy succulent glands of the ileo-colic mesentery. Colicky pains of short duration, coming on especially after food, were the principal symptom. They appeared to be due to spasm set up by the hypertrophied mucosa, which did not necessarily show any histological evidence of inflammation. The enlarged glands might cause slight tenderness over them. It seemed probable that their enlargement was due to absorption of toxins from the appendix. There was no apparent enlargement of glands elsewhere, nor of the tonsils. In diagnosis of chronic appendicitis Mr. Fletcher supported the emphasis laid by J. Sherren and others on the importance of a history of a preceding acute attack, starting centrally; and of viewing with suspicion any case in which the pain had started in, or had been confined to, the right iliac fossa. None the less there were exceptions. He had operated on not a few patients with acute appendicitis who insisted that the pain had started in the right iliac fossa, and this was especially the case when the appendix lay in an extra- or retro-cæcal position. Again, there were cases of undoubted chronic appendicitis where there had been no acute attack, notably of the type in which a fæcal calculus caused a mild inflammation of the mucosa surrounding it. Cases not conforming to Sherren's rule should be scrutinised with the greatest care and every other possible cause canvassed in turn, with the help, if necessary, of X rays, and always with a routine microscopic examination of the urine. No history and examination was complete which did not include in its survey the urinary, generative, digestive, and biliary systems.

The speaker reviewed 100 cases in which he had operated for supposed chronic appendicitis, and in all of which at least one year or more had elapsed before

inquiry was made. Sixty-eight, or just over two-thirds, had been cured of the pain for which they sought relief. Thirty-two patients had had some return of pain or some minor disturbances which precluded them from being regarded as definite cures. Errors of diagnosis, the majority being cases of tuberculous glands, accounted for 12 of these failures. Sixteen patients, five of whom had undoubted appendicitis also, had ptosis of, or congenital membrane formation in, the proximal colon, which was probably the cause of their renewed pain. It was significant that of these 16 patients 15 were females of whom 11 were young adults. Twenty-nine patients with true appendicitis had dyspepsia also. Of these, 22 were cured by appendicectomy. Twelve had the flatulent and 17 the painful type of dyspepsia. Of these latter, there was in eight cases a strong mimicry of gastric or duodenal ulcer in that the pain was of a severe gnawing, cramping, or gripping type, constant in its time incidence after food, the attacks lasting one, two, or more weeks, with periods of complete relief between. Six of these patients were entirely cured by removal of the appendix. The concurrence of attacks of dyspepsia and the lighting up of appendicular symptoms was noted in several cases.

Mr. Fletcher discussed the differential diagnosis between chronic appendicitis, pelvic, urinary, glandular, and cholecystitic, and proximal colon diseases, paying special attention to the latter, which was the most common source of error in the female sex. In speaking of cutaneous hyperasthesia in appendicitis, he said he had found it far more frequently involving the neighbouring halves of the tenth and eleventh right dorsal segments than any other area, and though the cæcum might possibly also be represented in those segments, he regarded such hypersensitiveness as a valuable confirmatory sign of appendicitis.

INFLUENZA.

MEASURES FOR ITS PREVENTION.

A WIDESPREAD epidemic of influenza is reported from Canada and the United States, where it began in the west about the middle of October. Although mild in form it has caused a considerable increase in the general death-rate and at least a million people were infected before the end of last year. Some concern is felt, therefore, lest it should soon appear in this country, and though the latest published returns (see p. 102) show but little rise in the number of deaths ascribed to the disease, the advent of a serious epidemic within the next few weeks is by no means unlikely.

The Ministry of Health has therefore re-issued to local authorities its useful memorandum [1] on the subject. As a full abstract has already appeared in THE LANCET (1927, i., 248), we will now do no more than refer to some of the main recommendations made.

Attention is, of course, drawn to the need for efficient ventilation and to the dangers arising when many persons are aggregated in sleeping quarters where there is insufficient space between head and head. At the same time it is suggested that temporary overcrowding in trains, trams, omnibuses, and places of entertainment is probably a more important factor than home overcrowding in spreading infection.

"During influenza prevalence, those who are able to do so will diminish their chances of contracting the disease by keeping away from all places of public resort or social gatherings. Most persons are able to avoid at least some occasions of forming part of a crowd or assembly without prejudice to their necessary occupations, and should do so."

Apart from the use of good nourishing food, whose value is obvious in warding off respiratory disease, the measures considered include gargling of the throat and nose, the wearing of face-masks, and protection by vaccines. Gargling may be useful, and a satisfactory antiseptic for the purpose is thymol (e.g., one full tablespoonful of compound glycerine of thymol in a tumbler of hot water). A cheaper gargle, probably as effective, is dilute permanganate of potash (1 in 5000). On present knowledge it is not regarded as desirable to wear face-masks, though they may be occasionally needed by those attending the sick. There is presumptive evidence, says the memorandum, that something can be done by the use of vaccines of suitable composition to lessen the risk of the attack being complicated by secondary infections. Vaccines may suitably consist of killed emulsions of pneumococcus, streptococcus, or Pfeiffer's *Bacillus influenzæ* separately or in combination, and though such direct evidence as the Ministry has been able to collect does not encourage an optimistic view of their value, there exists testimony by individual observers to their good effect in some cases.

On the precautions to be taken when attacked the memorandum states:—

"Continuing at work after the first symptoms appear is bad for the patient, and may be dangerous to others. Workers obviously ill should at once be sent or taken home. Where influenza is prevalent, no person should in any way be penalised for staying away from work, bona fide, for even a slight attack of influenza or any form of feverish cold. On the contrary, he should be expected and required so to do.

"At the first feeling of illness or rise of temperature the patient should *go to bed, keep warm, and seek medical treatment.* . . . . Relapses and complications are much less likely to occur if the patient goes to bed at once and remains there till all fever has gone for two or three days; much harm may be done by getting about too early. Chill and over-exertion during convalescence are fruitful of evil consequences.

"The early stages of an attack are the most infectious, but infection may persist throughout the illness, and isolation should be maintained at least till the temperature is normal. If the patient cannot occupy a separate room the head of the bed should, if possible, be screened off from the rest of the apartment.

"The virus of influenza is easily destroyed, and extensive measures of disinfection are not called for. Expectoration should be received when possible in a suitable receptacle in which is a solution of chloride of lime or other disinfectant. Discarded handkerchiefs should be immediately placed in disinfectant or, if of paper, burnt.

"The liability of the immediate attendants to infection may be materially diminished by avoiding inhalation of the patient's breath, and particularly when he is coughing, sneezing, or talking. A handkerchief or other screen should be held before the mouth, and the head turned aside during coughing and sneezing. The risk of conveyance of infection by the fingers must be constantly guarded against, and the hands should be washed at once after contact with the patient or with mucus from the nose or throat."

The rest of the Ministry's memorandum is devoted to the action to be taken by sanitary authorities to combat outbreaks. It deals with the questions of education of the public and profession, notification, closure of schools and places of entertainment, ventilation of trains, 'buses, and trams, disinfection, organisation of medical and nursing services, and institutional treatment. It is thought that schools may sometimes be closed with advantage in rural and small urban districts where the children do not mix much out of schools hours.

[1] Memorandum on Influenza (revised edition). London: H.M. Stationery Office. Pp. 14. 2*d*.

LORD NINIAN HOSPITAL, CARDIFF.—This Roman Catholic Hospital was founded in 1918 by the Dowager Marchioness of Bute in memory of her son, Lord Ninian Crichton-Stuart, who fell in the War. The announcement of her intention to place the management in the hands of trustees has led to the resignation of the entire nursing staff, on the ground that "the institution cannot be run under trustees." The nurses are Sisters of the Order of the Sacred Heart, and they believe that the new arrangements would hamper their work. Lady Bute has now set aside a substantial sum for the endowment of the hospital in perpetuity.

Reviews and Notices of Books.

FUNGI AND FUNGOUS DISEASES.

The Adolph Gehrmann Lectures. By Prof. ALDO CASTELLANI, K.C.M.G. (Hon.), M.D., F.R.C.P., Professor, Tropical Medicine, Tulane University, New Orleans; Director, Tropical Medicine and Dermatology, Ross Institute, London. Chicago: American Medical Association. Illustrated. Pp. 203.

IN an introduction to this admirable series Prof. Castellani says that "20 per cent. of all tropical diseases are due to fungi, and . . . diseases due to fungi are also not at all rare in temperate climates." There is no doubt that fungous diseases, if not on the increase, are at least more frequently recognised, both clinically and in the laboratory, than they were a decade ago, and no small part of the credit for this advance is due to Castellani's researches on mycology. The science of mycology is older than that of bacteriology, but took second place after the stir created by the discoveries of Pasteur and Koch, and is almost entirely neglected in the medical curriculum at the present day. The average reader will be discouraged in his attempt to make a close study of a subject which has so difficult a nomenclature. Even the dermatologist will find the going hard, but to him, as also to the pathologist who takes an interest in the practical side and the cultural proof of mycotic disease, this collection of reprints from the *Archives of Dermatology and Syphilology* will be found most stimulating. The first lecture, which occupies no less than 103 pages of closely printed text, is given to the fungi, their morphology, methods of culture, and classification. The second lecture (44 pages) deals with certain diseases due to fungi, including those of the tonsils and bronchi, and mycotic invasion of the nervous system. Cutaneous affections due to fungi—and these, as every dermatologist has come to realise, are much more common than was hitherto suspected—render the remaining 55 pages the most interesting and important of the series. Particular attention should be paid to the sections which suggest a possible cause of ano-genital pruritus and eczema. It would appear from some of the case records that this distressing and intractable affection does not always present a typical clinical picture; and it may require repeated microscopic and cultural tests by a skilled mycologist to determine its true nature and institute proper treatment. The text of these lectures is crammed with data, and we feel some sympathy for the medical student of the future who, when the subject of mycology is once more established in the curriculum, will be expected to grasp its fundamentals in the same way as his predecessor must master the elements of bacteriology to-day.

There is no treatise on clinical mycology in the English language which will stand comparison with this admirable survey of the subject up to the year 1926, when the lectures which form its pages were delivered.

AN INDEX OF DIFFERENTIAL DIAGNOSIS OF MAIN SYMPTOMS.

Fourth edition. Edited by HERBERT FRENCH, M.D., F.R.C.P. Bristol: John Wright and Sons. 1928. Pp. 1171. 63*s*.

THIS book has been out of print now for over five years, the third edition having been reprinted for the last time in 1922. Its reappearance will be welcomed. The index is compiled on the assumption that a particular symptom attracts special notice in a given case, and that the diagnosis has to be established by differentiating between the various diseases to which this symptom may be due. Thus, supposing a patient consults a physician or surgeon and presents some noticeable and perhaps isolated symptom or sign, for which there is no obvious cause, various paragraphs in the book provide a full list of the possible causes and the differential diagnosis of each is freely discussed. The sections on vomiting, aphasia, and swelling in the right iliac fossa provide typical examples. All vomiting is either central or reflex in its physiological relation to the vomiting centre; as central causes we find drugs, tobacco, uræmia, diabetes; as reflex ones we find three groups, gastric, general visceral—e.g., peritonitis—and central nervous—e.g., meningitis. Aphasia will be found under a section devoted to defects of speech, which differentiates between difficulty due to mental defects, aphasia proper, deaf-mutism, and dysarthria. Swellings in the right iliac fossa are similarly set out and described in proper contrast. There is at the end of the book also a subsidiary index of great length, being, in fact, almost one-quarter of the size of the rest of the volume. In this subsidiary index there seems to be set forth every subject for diagnosis under every possible heading; we are not quite clear as to the functions that this additional compilation of 227 pages is designed to serve.

The volume is admirably illustrated, there being now 701 illustrations, of which 179 are fully coloured. Among the uncoloured ones X ray prints are abundant and excellent. There is a special short paragraph on X ray methods in the last section in the book, wherein lipiodol injections into the lungs and uterus and the new methods of skiagraphy of the gall-bladder are well described and illustrated. Of the coloured illustrations those of various throat conditions (tonsillitis, quinsy, and faucial diphtheria), of acute inflammatory conditions of the eye, of actinomycosis, and of the face in mitral stenosis are noteworthy. Contributions are made by 20 individuals, the lion's share of the work falling to the editor.

The fund of knowledge contained in this volume is incalculable, and at the same time it is easy and pleasant to read.

DIE CHIRURGIE.

Edited by Prof. M. KIRSCHNER and Prof. O. NORDMANN. Lieferung 19. *Die Vorbehandlung, der Verband und die Nachbehandlung bei chirurgischen Eingriffen.* By Prof. O. NORDMANN. *Die plastischen Operationen der Haut.* By Dr. K. TIESENHAUSEN. Berlin: Urban and Schwarzenberg. Pp. 209. M.14.

IT is significant of the trend of modern surgery that the editor of a large system should himself write the sections dealing with pre- and post-operative treatment. Prof. Nordmann has compressed this vast subject into 110 pages, but his article is notable for its breadth of view, its sane outlook, and practical value. He lays stress upon the necessity for a full and fairly complete examination of the patient before submitting him to an operation. Only in this way can risks be estimated and dangers anticipated. Prof. Nordmann describes those methods which he has found to be helpful, criticises from experience others which he has discarded, and does not hesitate to point out deficiences in our knowledge of the treatment and prevention of complications such as thrombosis and post-operative lung affections. His views on the preparation of patients with pyloric stenosis, jaundice, heart affections, kidney diseases, to take a few examples, are all interesting, and the very emphasis laid upon the necessity for careful consideration of the patient from every point of view is likely to stimulate interest in an important aspect of surgery.

Dr. Tiesenhausen has written a satisfactory account of plastic skin surgery. The first part is general in scope, and is followed by a special part in which individual operations are described. Some of the less known and rarely practised procedures find a place in this section—for example, the substitution of a toe or finger for a missing thumb, and though the accounts are fairly adequate their value would have been enhanced if more details had been given. However, the reader can always refer to the original sources of information on the rare occasions when

specially detailed knowledge is required, and the bibliography at the end of the work will tell him where to look.

THE HARVEIAN ORATION, 1928.

Cardiovascular Diseases since Harvey's Discovery. By Sir HUMPHRY ROLLESTON, Bart., K.C.B., M.A., M.D., F.R.C.P., Regius Professor of Physic, Cambridge. London: Cambridge University Press. 1928. Pp. 149. 3*s.* 6*d.*

IN choosing this subject for his Harveian oration Sir Humphry Rolleston made a contribution to the history of medicine worthy of the tercentenary of publication of Harvey's famous work. Had he desired an alternative title he might with justice have called it "Who was Who in Cardiology." There are four chapters which deal respectively with the anatomical, clinical, instrumental, and physiological aspects of the subject, each chapter being followed by a bibliography giving proof of the amount of time and labour which the author must have devoted to compiling his oration. An author and a subject index add greatly to the value of the book as a work of reference.

BIBBY'S BOOK ON MILK.

Sect. II. *The Law relating to the Sale of Milk.* Twelfth edition. Liverpool: J. Bibby and Sons. 1928. Pp. 487. 30*s.*

THE miscellaneous contents of this section of Bibby's Book on Milk include a historical introduction, suggestions for the guidance of local authorities, analysts, milk vendors, and others, hints for the defence against milk prosecutions, the text of the Sale of Food and Drugs Acts and similar legislation, notes on the statutes, a summary of the case law, and a collection of statistics, departmental circulars, and statutory rules and orders. While this volume, entitled the Law relating to the Sale of Milk, is not a lawyer's text-book in anything save price, it gathers together much information not otherwise readily available. An editorial note for preoccupied readers explains that one object of the book is to expose the injustice of the present law and the need for its amendment. First, it is said, the law ought to be changed so as to separate the attempt to punish fraudulent adulteration from the attempt to control the quality of milk. Secondly, the fraudulent sale of adulterated milk being a mere form of theft, it is contended that the prosecution should be made to prove its facts and to establish the criminal intention of the accused in the ordinary way. Thirdly, if the quality of milk is to be controlled (and a policy of laissez-faire is nowadays in this respect unthinkable), the suggestion is made that the control should not be associated with criminal procedure.

These propositions are, of course, controversial. Though the powers of local authorities are unevenly exercised, and though our system of controlling milk-supply still tolerates too much tainted milk, we have reached improvement largely by the establishment of a hard-and-fast standard enforced by criminal prosecutions. It is true that the element of criminal intent is not insisted upon; but the community is entitled to protect itself in sanitary matters by weapons inappropriate in other circumstances. The householder whose chimney takes fire is liable to a fine however innocent his mind may be of criminal motive. The farmer or milk vendor is treated in the same summary fashion, but perhaps with better justification. Milk below standard may be pure and pure milk may be below standard, but it is doubtful if the good farmer and the honest milkman are in danger of heavy penalties in the course of their business. The reports of important cases are well set out though they naturally vary in length. The authors of the book deserve sympathy in that the Sale of Food and Drugs Acts, which they print in full, have been swept away (except in Northern Ireland) a few months ago by the consolidating Food and Drugs (Adulteration) Act of 1928. An addendum slip mentions this fact, and says the text of the new statute will be found in a supplement (Supplement 8, pp. 31, 9*d.*) which, in fact, has since reached us, together with Supplement 7, pp. 7, which gives an account of the case of Palmer *v.* Houson (Presumed Watering). The passing of the 1928 Act makes no substantial change in the law and leaves the decided cases untouched, but it alters the form of the statute law and upsets all previous references thereto.

MONGOLISM.

By KATE BROUSSEAU, Docteur de l'Université de Paris; Professor of Psychology in Mills College, California. Revised by H. G. BRAINERD, M.D. Baltimore: Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1928. Pp. 210. 20*s.*

ALTHOUGH this handbook is based upon ten years' personal experience of the care of mental defectives, its object is not so much to provide a first-hand authoritative treatise on the subject as to collate and compare theories of the many observers who have written on this difficult branch of psychiatry. Its bibliography is very full, and as a summary of the literature alone it is of great value. It also contains many carefully compiled tables of anthropological and psychological data obtained from mongols, is illustrated with many excellent photographs, and includes much practical advice on the management of these patients. The author's conclusions from the available statistics do not bear out many of the most accepted theories as to the ætiology; she cannot agree that the condition is due to reversion to a primitive mongol type, to parental alcoholism, tuberculosis, syphilis, or neurosis, to aged parents or reproductive exhaustion. She infers, as many other workers have been forced to do, that the cause must lie in some obscure disturbance of the ductless glands. Some endocrine disturbance, she says, may be found in every mongol. This opinion is not shared by Prof. Hans Curschmann in his recent work "Endokrine Krankheit"; he admits that the condition probably bears some relationship to endocrine disturbances, but holds that it is certainly not due to them.

EVOLUTION.

How You Began: a Child's Introduction to Biology. By Mrs. AMABEL WILLIAMS-ELLIS. With two prefaces by J. B. S. HALDANE. London: Gerald Howe, Ltd. 1928. Pp. 96. 2*s.* 6*d.*

IF anyone wants to teach a child that during the course of his individual development in his mother's uterus he has gone through the various stages of his ancestral evolution (or perhaps it should be "her," for little girls are believed to have more intellectual curiosity than little boys) they will find an admirable guide in this book. Most people will prefer that he or she should learn the Bible and the multiplication table. Like many books professedly written for children, Mrs. Ellis's will be most useful for grown-ups, and they are likely to read it with profit.

CLINICAL ASPECTS OF THE ELECTROCARDIOGRAM.

Second edition. By HAROLD E. B. PARDEE, M.D., Assistant Professor of Clinical Medicine, Cornell University Medical School. London: William Heinemann, Ltd. 1928. Pp. 242. 25*s.*

WHEN electrocardiography was first introduced its most obvious application to clinical medicine was in the diagnosis of the different types of cardiac arrhythmia. Since then our knowledge of the clinical aspect of these disorders has advanced considerably, and now in the majority of cases instrumental aid is no longer necessary for their recognition. Clinical electrocardiography has thus entered on the second phase of its career. It is being used to supplement the other methods of diagnosis in providing evidence

of those myocardial changes which fail to give rise to abnormal physical signs. In the various types of angina in particular the objective evidence of myocardial disease is often scanty, if not entirely absent, and it is in such cases that an abnormal electrocardiogram is of the greatest value. Some of these abnormalities, such as the changes which follow coronary occlusion, are now well recognised; but there are many features of abnormal records the significance of which is still obscure. A useful summary of the present position of our knowledge is given in Dr. Pardee's book. The author devotes four chapters to the description of the various abnormal features which are liable to appear in the auricular and ventricular complex. These chapters will be of interest to physicians who are already conversant with modern work on the diagnosis of heart disease. Another section of the book gives a clear and concise description of the more common electrocardiographic findings in disorders of rate and rhythm. The author points out that there are two groups of people who misjudge the value of this particular method of examination. The one group believe that electrocardiography can tell everything, and the other that it can tell nothing of practical importance. To both of these his book should prove a salutary corrective.

Two concluding chapters are devoted to certain theoretical considerations and to technique. With one or two exceptions, such as the statement on p. 129 that vagal pressure *never* fails to slow the ventricular rate in cases of auricular flutter, the views expressed are those generally held by workers in this field of medicine. The illustrations are well chosen and their reproduction is equally satisfactory.

AMERICAN MEDICAL ASSOCIATION OF VIENNA.

Twenty-fifth Anniversary Number. Pp. 306. *Ars Medici*. The Journal of the A.M.A. of Vienna. Vol. VI., No. 11. Published monthly in Vienna, IX. Spitalgasse 1 A.

THE first of these publications sets out the progress that has taken place in the work of the American Medical Association of Vienna, since it was established in that city at a Thanksgiving Day banquet in November, 1903. At its formation the Association had only 35 members; at present we learn that it numbers over 6000, more than 1000 having joined within the past two years. All medical men coming to Vienna for study are invited to enrol their names in a registration book kept by the Association, in return for which they will be furnished with information of the sort that they will require in a foreign city, and will be allowed free access to a reading-room and a reference library, and an institution where they will have opportunities both for scientific discussion and social intercourse. The bulk of the anniversary number consists of a detailed list of the clinical and pathological courses which can be arranged through the Association, with full names of the professors or lecturers, indications being given as to where the instruction may be met with. All the courses are conducted in the English language except where German is specifically mentioned as the only language employed.

Ars Medici is the latest achievement of the Society—its official monthly organ. It contains abstracts and reviews of foreign, especially Austrian and German literature, as well as particular notes on the activities of the Association.

ST. BARTHOLOMEW'S HOSPITAL REPORTS.

Vol. LXI. London: John Murray. 1928. Pp. 260.

THIS year's volume contains, besides domestic matter and abstract reports of the transactions of the Paget Club and the Abernethian Society, 17 original papers with many excellent illustrations. Of these the first seven deal with the respiratory system. Prof. F. R. Fraser contributes a short paper on dyspnœa, and Dr. F. G. Chandler and Dr. J. V. Sparks a practical article, illustrated by eight very clear X ray photographs, on the diagnosis of bronchiectasis by means of lipiodol injections. Pneumothorax is fully discussed in three contributions. Mr. J. E. H. Roberts describes the results of collapse therapy in eight cases of bronchiectasis, Dr. F. H. Young deals with the use and control of artificial pneumothorax in ambulant cases of tuberculosis, and Dr. R. Hilton with the more general aspect of the operation, including its history. Dr. C. Langton Hewer, in a paper on anæsthesia in thoracic operations, signifies a preference for nitrous oxide and oxygen, with differential pressure if the pleural cavities are opened; in extreme cases of obstruction from tumour he induces anæsthesia by chloroform and maintains it by the endotracheal method. Mr. Cortlandt MacMahon, the instructor of speech defects and breathing exercises at the hospital, describes the exercise treatment of empyema. Two cases of cystic serous meningitis of the posterior fossa, originating in the ear, are related by Mr. T. H. Just; Dr. E. Arnold Carmichael assesses the diagnostic value of the examination of cerebro-spinal fluid in ear and nose affections; and Mr. J. P. Ross writes on a number of cases of various intracranial injuries. Mr. J. Basil Hume reports the unfavourable results of the lead treatment of cancer at St. Bartholomew's. An unusual case of heart-block, with cardiograms, is described by Dr. Geoffrey Bourne; 50 cases of acute osteomyelitis are analysed by Mr. J. P. Hosford. Mr. Alexander Roche writes on torsion of the spermatic cord, giving case notes, tables, and bibliography, and illustrating his article with several microscopical pictures and a coloured drawing. Mr. R. T. Payne gives his experiences with the now popular sclerosing treatment for varicose veins; Mr. T. M. Thomas describes nine cases of femoral aneurysm, and Dr. E. M. Allott one case of rat-bite fever. As usual, the book is well bound and clearly printed.

JOURNALS.

INDIAN JOURNAL OF MEDICAL RESEARCH. Vol. XV., No. 2.—This number contains 26 papers of perhaps exceptional merit. H. E. Shortt, A. C. Craighead, R. O. A. Smith, and C. S. Swaminath describe transmission experiments in kala-azar with *Phlebotomus argentipes* which were, unfortunately, negative, and attempts to infect hamsters with *Leishmania donovani* by the oral and conjunctival routes similarly failed.—F. P. Mackie and S. N. Gore describe a hitherto unrecognised bacillus isolated from cases of sprue.—J. A. Sinton, in conjunction with P. J. Barraud, is responsible for morphological studies on some species of phlebotomus, and together with W. Bird and W. B. F. Orr has studied malaria with special reference to treatment.—P. J. Barraud contributes a study of the revision of the culicine mosquitoes of India.—R. N. Chopra collaborates with S. Ghosh and N. R. Chatterjee in a number of papers on the action of antimony compounds, concluding that it is doubtful whether urea stibamine is a compound of the nature suggested by its discoverer.—Contributions on Indian anophelines include papers by I. M. Puri on *Anopheles jeyporiensis* James and *A. moghulensis* Christophers, and on the relationship of certain morphological characters of anopheline larvæ to the classification of Indian anophelines in general. Bruce Mayne has found that *A. subpictus* can serve as host for the parasites of bird malaria.—E. W. H. Cruickshank and Sheonath Prosad have studied the action of insulin on the free muscle sugar of the normal and diabetic heart.—R. B. Lloyd and S. N. Paul have constructed protein graphs in kala-azar, both in treated and untreated cases.—G. R. McRobert has studied the hydrogen-ion concentration of the alimentary canal of the albino rat and has made observations on the size of the spleen, his results being in close accord with those of Barcroft.

THE LANCET.

LONDON: SATURDAY, JANUARY 12, 1929.

THE KING'S ILLNESS.

IT is now generally recognised that a startling improvement in the KING'S condition is not to be expected, but we are happy to say that no unfavourable developments have occurred during the past week. Events have justified the forecast that there would be ups and downs and that the course of the illness and of recuperation would consist in an increasing predominance of the former over the latter. Such progress, though slight, is definitely being made, and our readers will be especially glad to learn that the average rate of the pulse has diminished and that it is less easily disturbed by outside influences. In weighing the significance of these facts it must not be forgotten that there is still difficulty in feeding, wasting, and exhaustion, and that these cannot be overcome without long effort; especially is the exhaustion produced by the gallant and extended struggle for life, an element in the case which has throughout given the gravest anxiety. It is obvious that the moves forward at best will be slow, and that considerable periods may pass without any notable changes. For this we must be prepared, though it may not be easy for those who are watching the current of events to achieve an even frame of mind. From primitive times it has been the nature of mankind to demand miracles and to seek signs, and during a period of strain the press of the country has inevitably reflected this requirement. In the diligent search for some new thing an unwelcome prominence has lately been given to one doctor and to a new remedy, or rather to an old remedy revived in a new form. We offer our sympathy to Prof. DODDS, whose valuable biochemical investigations have been given too wide a significance in many quarters. Although he was able to give much assistance by analysis and by contributing to discussions on the data thus obtained, we are authorised to say that his advent on the scene did not coincide with any dramatic change either in the patient's condition or in the treatment adopted. His distinguished work at the Middlesex Hospital is so well known to the medical profession that he need fear no misunderstanding of the situation among his colleagues. But it is regrettable that among those who are less well-informed some of the speculations which we have read may have a misleading tendency. When such full information has been given regularly in the bulletins upon all the essential points in the story, it must be dangerous, however strong the temptation, to rely upon unauthenticated stories for views or judgments.

THE TREATMENT OF EARLY BREAST CANCER.

THE technique of the classical operation for cancer of the breast has long been standardised at a very high level of efficiency, and it is difficult to see how it could be further improved unless the whole paraphernalia of scalpels, clamps, and ligatures appertaining to a cutting operation are superseded. Many surgeons, however, are devoting attention to the development of a surgery of access, since, as Mr. SAMPSON HANDLEY pointed out in his Sylvanus Thompson lecture, published in our columns last week, a combination of surgery and radiotherapy may well lead us further than either could go alone. Such a view does not justify the exaggerated statements which have appeared recently in the lay press, where radium has been described as a "cure" for cancer which is likely to supplant operation. Such a statement is certain to do much harm, since it may induce patients to refuse an operation when operation is advisable; and it should not be made even for the wholly praiseworthy cause of collecting money from the public for the purchase of radium. Radiotherapy is no more a cure for cancer than is operation; it is a treatment the efficiency of which, like that of operation, depends upon the stage of the disease at which it is applied, and upon an understanding of the pathology of the condition. It would seem a truism to say that the successful treatment of a disease depends upon consideration of its pathology, were it not for the statement made by Mr. DUNCAN FITZWILLIAMS at a meeting of the Section of Surgery of the Royal Society of Medicine, reported on p. 74. He claimed that in the early stages of carcinoma of the breast the condition can be cured by a partial operation, removing only the growth and leaving the rest of the breast tissue behind. We believe that this procedure would be generally condemned as a retrograde step; indeed, this was made clear by some of the speakers at the discussion; but since the question has been raised, it may be timely to amplify some of the objections that were raised to a partial operation.

Only a few months ago Dr. JANET LANE-CLAYPON published a valuable monograph[1] in which she collected and classified the end-results of over 2000 cases of breast cancer treated at different hospitals by different types of operation, including the partial operation (removal of tumour only) as applied to so-called "early cases." This investigation, which was published by the Ministry of Health, was presumably carried out for the benefit of surgeons, but the lessons which it contains have apparently not yet been generally learned. An early case of breast cancer is, by definition, one in which the disease has not yet spread to the axillary glands. If such a case is treated by removal of the tumour only, the answer to the question whether the disease has, or has not, spread to the axillary glands rests entirely on the clinical examination of the axillary glands. On this point the figures quoted by Dr. LANE-CLAYPON are relevant. They show that

[1] Reports on Public Health and Medical Subjects, No. 51. Late Results of Operation for Cancer of the Breast. London: H.M. Stationery Office, 1928, and THE LANCET, 1928, ii., 507.

negative clinical findings for the axillary glands are incorrect in over one-half of the cases; that is, in spite of the glands not being palpable, they were, in fact, found to be invaded when examined microscopically. She points out that in just those cases which might be the most favourable a false clinical impression of the state of these glands may prejudice the patient's best chance of survival, since the radical operation is not always performed if the surgeon cannot detect enlargement of the axillary glands, and some practitioners still regard a case as non-malignant unless the glands of the axilla are palpable. It is admitted that the survival rates in those early cases where breast only or tumour only was removed approximate closely to those obtained for the radical operation; it may be conceded that in the majority of these cases the whole of the cancer was in fact removed, and therefore no recurrence was to be anticipated. If, therefore, the surgeon could be certain of removing the whole of the cancer in a conservative operation the results should be just as satisfactory as with the radical operation. Unfortunately, however, the palpation of the axillary glands has been proved to be unreliable, if negative, and to be incorrect in over half of the cases. In other words, it is impossible to diagnose with any degree of certainty an "early" case of breast cancer. Hence there can be little doubt that even in "early" cases there is a considerable risk if the radical operation is not performed.

There is yet another reason why, in breast cancer, removal of the tumour only is a dangerous gamble. The work of Sir LENTHAL CHEATLE, based on the histological examination of sections of the whole breast, has shown that the presence of a malignant new growth in one part of the gland is frequently associated with pathological changes in other parts, which represent a precancerous condition. Such a view is in accord with the results of recent work on experimental carcinogenesis. If, therefore, only the tumour is excised, that part of the breast which remains behind may contain several foci for the new development of further growths. Clinically, such a result would be described as a local recurrence, although it is really a new cancer, and Dr. LANE-CLAYPON'S figures show that in this type of operation recurrences are not infrequent. Sir LENTHAL CHEATLE'S method of studying whole sections of the mammary gland has shown the condition of "early breast cancer" to be a much more complex one than has hitherto been suspected, and has given valuable information on the types of epithelial hyperplasia which can be regarded as a precancerous condition. In fact, the many advantages of this method of ascertaining the state of the epithelium and the connective tissues of the breast in conditions which call for operative interference are so obvious that its general acceptance by clinicians and pathologists in this country and its extension to other organs is overdue. A recent Report of the Proceedings of the American Association for Cancer Research [2] shows that the value of the method has been recognised there, and by no less an authority than Prof. JAMES EWING. A change in nomenclature is always difficult to impose on a conservative profession, but Sir LENTHAL CHEATLE has, we think, made out a good case [3] for a drastic revision of classification of mammary swellings, and we commend the outcome of his arduous labour as a good starting ground for workers on breast physiology and pathology.

[3] THE LANCET, Jan. 5th, 1929, p. 37.

THE HEALTH OF THE YOUNG WORKER.

IT has been realised for some time that the extensive provisions made by the Government of this country for conserving the health of its workers leave two very important gaps unbridged. The first of these is the period immediately before school age, and this was the main problem to which the Board of Education's annual report drew attention last year.[1] Along the lines which Sir GEORGE NEWMAN then indicated some progress has been made, as he relates in this year's report (p. 96). There are quite a number of nursery schools where the toddler and the child under five can spend their days "playing at work" in a healthy atmosphere, with good food, and where they can learn the early adaptation to life which will help them when school comes along. Although so far only weakly children and those from poor environments have been selected, yet an attempt to trace the subsequent history of the nursery scholar has shown that all have held their own—in their teachers' words they have been found "alert, eager to learn, well-behaved and equipped with habits and attitudes which made for progress and happiness." The solution of the problem may have been arrived at, and we must hope that such accommodation will be extended until all who can benefit from the provision can be accepted at nursery schools.

The outlook for the "post-school child" is less happy than that for the "pre-school child," and Sir GEORGE NEWMAN devotes considerable attention this year to the position left by national medical services between the school-leaving age and the age when the young worker can be enrolled under the National Health Insurance Act. The child who leaves school at 14 nowadays is healthier, heavier, taller, cleaner, and altogether a better and more promising individual than was the child who left five or ten years ago. To-day this young citizen loses less time from his work owing to sickness; there is less malnutrition, less tuberculosis, less glandular disease, less defective sight and hearing, better teeth. To a certain extent —though not yet universally—he has received instruction on how to keep fit, and year by year the education authorities strive to make this teaching more practical and to instil the habit of hygiene more thoroughly, so that the adolescent may keep his health into maturity. Yet there is a place where the promise is not fulfilled; in the two or three years succeeding the leaving of school the average boy and girl tend to go backward in health. With the best of teaching at school it is, perhaps, too much to ask of them that they should maintain hygienic habits without any encouragement or assistance, for, as Sir GEORGE NEWMAN points out, the adolescent is a gregarious animal and he will follow his herd. Apart from movements such as the Boy Scouts and Girl Guides, there is no organisation for stimulating healthy living. The young worker is nobody's business. The Committee on Education and Industry has recently issued a report dealing with the public system of education in relation to trade requirements.

[1] THE LANCET, 1927, ii., 1245.

This report urges close and continuous coöperation between the life of the schools and the life of the office or workshop, so that the two would no longer be disconnected episodes, but from both sides would be regarded as a single period in the training of the citizen. From the point of view of health continuity is a paramount necessity. This second gap is bridged in certain cases—relatively few but extremely important—by a factory welfare scheme. Large and progressive firms are realising more and more that it pays to provide medical advice and sickness benefits for their employees, and in many cases the firm's doctor is in close touch with the school medical officer. He examines the young employees periodically, treats minor ailments, and sees that defects are remedied. Were such provision for continuity universal, the gap would be effectively bridged; unfortunately this occurs in only a very small proportion of the young people who leave school every year, and the more efficient it is the more carefully is the entrance guarded, so that in effect it is the healthiest and strongest who receive this care. Other lines along which a bridge might be built are indicated by the juvenile employment and advisory bureaux and the work of the certifying factory surgeon. In Birmingham, information from the medical cards of school-leavers is filed by the employment bureau, so that unfitness for any particular kind of work is recorded, and similar coöperation has been arranged in other districts. The examination of the certifying factory surgeon is simply one to ascertain fitness for a given employment; it cannot be regarded as a satisfactory review of the child's health. Where the certifying surgeon is also a school doctor, and still more, where he is also the medical officer of a firm's welfare scheme, continuity between school and factory is attained; with this situation in view the Board of Education is anxious to ensure closer coöperation between school inspection and certifying inspection, and is willing to transmit medical records for this purpose.

It is obvious that the present position offers several possibilities, but that the establishment of a really satisfactory scheme of care for the young worker presents grave administrative difficulties. We may anticipate an increasing number of factory welfare schemes and an increasing sense of need for coöperation between individual certifying factory surgeons and school medical officers. This, however, is not enough. There should be some official scheme, comparable in excellence with the School Medical and Infant Welfare Services, to ensure that the health of our growing population at the critical ages of 15 and 16 shall not depend on individuals or vary in different localities. Most important of all, perhaps, the scheme must include supervision of the health of those who are not actually engaged in employment. This is brought home to us by the present lamentable situation in the mining districts. It is no unusual thing to meet young men there who, since the time they left school six or seven years ago, have never done a day's work, through no fault of their own. However greatly the young worker may need medical supervision there can be no doubt that the young workless boy and girl need it far more. Idleness is the most unhealthy environment an active organism can have, and its effects are not confined to the purely psychological field, as every practitioner knows. Idle or employed, the period of adolescence is perhaps of all periods that when to dispense with medical help can be least afforded, and the opportunity for obtaining health-teaching at this critical age should be forthcoming.

MATERNAL MORTALITY.

SINCE 1917 every puerperal death occurring in Aberdeen has been notified to and investigated by the local authority, this scheme having been instituted by Prof. MATTHEW HAY when he was medical officer of health of the city. His successor, Dr. PARLANE KINLOCH, with the assistance of Dr. J. SMITH and Dr. J. A. STEPHEN, has thus been able to collect, over a decade, statistics of 252 deaths occurring in 37,984 confinements. They have reviewed this material in a report on Maternal Mortality in Aberdeen, 1918–27 (H.M. Stationery Office, 1928, pp. 60, 1*s.*). No definite relation between environmental conditions and puerperal mortality were revealed by the inquiry and no new light was thrown on the influence of personal factors such as age, occupation, or habits of the mother, illegitimacy, or syphilis. The hæmolytic streptococcus was incriminated as the most important bacterial cause of puerperal sepsis, but on theoretical grounds little encouragement is given to the hope that any general scheme of prophylactic immunisation against this group would be feasible at present. On the other hand, statistical evidence was obtained of the value of antenatal services in reducing maternal mortality, and the expansion and improvement of these services is considered highly desirable.

The most interesting analysis concerns the comparative maternal death-rates in the practices of doctor, midwife, and institution. Table XII. shows that the death-rate per 1000 maternity cases delivered by midwives is 2·8, by doctors 6·9, in institutions 14·9. This last figure, which includes only cases untouched before admission, is surprisingly high; it is attributed by the authors to contagion—the term being used to embrace all the channels by which any droplet or spray infection, such as a streptococcal infection, is spread. The suggestion is not that infectious mucous secretions or purulent discharges could possibly be conveyed by trained attendants directly from uterus to uterus, but that a carrier may spray streptococci on to sterilised hands or instruments and these in turn infect the maternal passages. On this theory outbreaks of puerperal fever could be materially diminished in number and gravity by restricting the number of patients admitted to each ward and spacing their beds.

A suggestive fact is that there were no deaths among the 445 midwife cases in which forceps were used by the doctors called in to help. The authors discuss and reject the argument that the higher puerperal death-rate in the practice of doctors is necessarily due to trauma caused by premature instrumental interference, and hold that this is more likely to be due to contagion spread by carriers, doctors being more liable to become streptococcal carriers than midwives. Criticism of this and other conclusions will doubtless be welcomed by the compilers of this report, whose constructive scheme for the development of a new midwifery organisation will not escape dissent. But the figures provided are of the utmost value, and if they prove to be typical may well form the basis of reform of the midwifery services of Great Britain.

ENLARGEMENT OF ALTRINCHAM GENERAL HOSPITAL.—Prof. A. H. Burgess, of Manchester, has just opened an enlargement of this hospital, which has cost £10,000. The additions consist of a four-storey block with a male surgical ward, two private wards, a children's ward of 12 beds, and an enlarged operating ward.

Annotations.

"Ne quid nimis."

PUBLIC HEALTH AND LOCAL LEGISLATION IN 1928.

As has often been observed, our local Acts contain experimental legislation which, if found satisfactory in a limited area, can afterwards be extended to the country at large. In other words, what a local Act says this year a general Public Health Act may say in ten years' time.

The chief innovations in the local legislation of 1928 seem to be visible in the Sheffield Corporation Act, whereof several clauses may furnish useful precedents. The corporation, for instance, is authorised to construct inspection chambers at its own expense for the purpose of examining the nature of the discharge into sewers from manufacturing premises; in addition to the power to prevent the discharge of solids and offensive liquids into sewers the corporation has taken power to provide plant and buildings for treating and utilising refuse. Another clause allows the corporation to require the conversion of all other kinds of closet into ordinary fresh-water closets, cess-pits being got rid of, and the corporation bearing not less than one-third of the cost. Other novel provisions in the Sheffield Act belong rather to local government than to public health; by-laws, for instance, may regulate the thickness of garage walls and the providing of projecting hoods over garage openings; a £50,000 fund for land purchase may be formed with a contribution not to exceed a twopenny rate from the ratepayers' pockets annually; and, as a matter of organisation, the power to delegate authority to committees is extended. London and Rotherham, as well as Sheffield, have taken powers for the removal of infirm and diseased persons to institutions on an order by the justices. At Rotherham a justice's warrant may now authorise a medical officer of health to enter any premises where it is believed that there is dangerous infectious disease. The extended definition of infectious disease is among the new health provisions of a number of local authorities—Dartmouth, Exeter, Caerphilly, Llandudno, Cleethorpes, and Bridgwater, as well as Sheffield. The urban district council of Cleethorpes has taken power to appoint deputies to various officers including the medical officer of health. Other more familiar features of various local Acts of 1928 are those requiring the giving of information to medical officers, or requiring laundrymen's names to be furnished, or (as at Stoke-on-Trent) requiring dairymen to furnish lists of their customers. Llandudno, Cleethorpes, Sheffield, and Bridgwater now have powers for the municipal supply of antidotes; other forms of municipal activity are the London County Council's powers as to golf courses and Blackpool's to provide and run an aerodrome. It is nowadays hardly necessary to mention common clauses such as those as to tuberculosis (disinfection of premises and prohibition of infected persons handling food), or schools (parent to notify head teacher of child's infectious disease, and power to close Sunday schools or entertainments during epidemic), the cleansing of filthy premises, the inspection of stables, and the removal of dead bodies. In addition to the now almost universal legislation in respect of ice-cream and potted meat manufacture, Sheffield has taken power to refuse the registration of premises for such manufacture. An Exeter precedent is worth noting; the corporation is to register not only the premises used for ice-cream manufacture and sale, but also the manufacturers, vendors, merchants, or dealers themselves. As the Select Committee on Local Legislation observes in its last report, if registration applies to premises alone, a dealer can, after complaints against his premises, move outside the borough and bring in ice-cream manufactured under insanitary and unsupervised conditions. Cleethorpes has arranged for the registration of persons dealing in shell-fish, Dartmouth for regulating fried-fish shops, and Dudley for prohibiting the inflation of meat carcasses. In a number of areas food poisoning is made notifiable. Exeter has fresh powers of closing registered slaughter-houses—e.g., when the premises have been unused for six months.

Details of these and other items are to be traced in the official index to the local and private Acts of the session, published by H.M. Stationery Office (price 1*s.* 6*d.* net). This publication covers the main session of 1928—i.e., that which ended in August. Some progress was made with other proposals for local legislation during the autumn session which was adjourned on the eve of Christmas, but the Bills then dealt with must wait till 1929 for their chance to pass into law.

MALARIA IN CORSICA.

THE ill-effects of malaria in Corsica have led to a series of flying visits and reports by experts, such as those by E. Roubaud and M. Leger in the spring of 1921, and by the brothers E. D. and E. T. Sergent, with L. Parrot and A. Donatien, in the autumn of the same year. Again, in 1922, the Société de Pathologie Exotique pressed the urgency of the problem on the French Government, who in turn requested the League of Nations to conduct an independent inquiry—effected by E. Marchoux and L. Raynaud in 1925. Finally, in 1926, mainly under a subvention from the Division of Hygiene of the Rockefeller Foundation, the policy of hurried inspections gave place to a continuous investigation under the general direction of Prof. E. Brumpt, and consisting of a laboratory at Bastia, in the north of the island, outside the malarious zone, and a dispensary at Porto Vecchio within it. An interim report on this important work is now issued.[1]

After sketching the history of malaria and anti-malarial measures in Corsica, Prof. Brumpt's report deals with matters as they are. The population is just over 250,000, yet outside the island are twice that number of Corsicans, valuable members of the French Colonial administrations. Within the island an arresting feature is the extent of the daily or seasonal migration from the malarious eastern coastal plain to the healthier hills. For example, of the 4500 persons classed as inhabitants of Porto Vecchio, never more than 2000 live there, the figures in the malarious season falling to 600, while malarial infection, established by the finding of plasmodia, is four times greater in those who stay than in those who flit. All three species of plasmodia are present, the dangerous subtertian, the quartan, and the tertian prevailing in that order. The wide coastal marshes breed anopheles even when the salinity is as high as 26·32 g. to the litre, but where iron causes an irridescent scum, larvæ are absent. Nearly all anopheles are *A. maculipennis*, few adults have been found infected, and the inquiry shows that, as elsewhere, hibernation is by impregnated females, not by eggs as had been locally suggested. As a larvicide, dusting with Paris green has been found most efficient, yet the extent of the water surface to be covered is held to preclude its general use. The employment of an aeroplane for the purpose, well reported on from the United States, is not considered, but from the description of the country would seem to hold great promise. Local conditions are considered unsuited for oiling, but *Gambusia holbrooki*, introduced from America and bred at Bastia, has been strikingly larvicidal in nearly every local type of water. A screen of animal houses is believed to have been of marked value against attacks of the adult insect in certain cited instances. Quinine, it is urged, should not be issued wholesale for use as a general prophylactic. Its action is more economically concentrated on the infected.

The scheme in existence aptly materialises the advice of the first subcommittee of the Malaria

[1] La lutte contre le paludisme en Corse. Paris: Masson et Cie. 1928. Pp. 94. Fr.16.

Commission of the League of Nations (see THE LANCET, 1928, i., 664) in the right selection of a leader, giving time for his schemes to fructify in special research into local conditions, and in the application of those means of prevention which that research suggests as being the most promising for that locality.

NITROUS OXIDE AS A SUPPORTER OF COMBUSTION.

THE power of nitrous oxide to support combustion is often ignored, if indeed it is known at all. A suggestion was recently made in our own columns, for instance, that the gas might on emergency be used instead of compressed air to avoid the possible risk of concentrated oxygen when liquid paraffin is employed for lubrication. Yet the fact is that nitrous oxide contains double the proportion of oxygen present in atmospheric air and in a form which is readily available for combustion. The idea seems still to survive that nitrous oxide is inert, much in the sense that nitrogen itself is inert, although Hewitt states in his text-book, "When a burning body is placed in the gas the latter is decomposed and combustion is supported." The risk may be put a little more strongly than that. Prof. H. H. Dixon has shown[1] that in some combinations nitrous oxide helps to form an explosive mixture more readily than does oxygen itself. Testing ethylene and propylene mixed with air, oxygen, or nitrous oxide, Dixon found that the ignition points were actually lower with nitrous oxide than with oxygen. Nowadays when mixtures of ether or ethylene with nitrous oxide are so frequently employed for general anæsthesia, it should not be forgotten how readily nitrous oxide provides material for explosion under favourable conditions of temperature and pressure.

HISTOLOGY AND PROGNOSIS IN CANCER.

OF late years a good deal of attention has been paid to the relationship between the histological character of a malignant growth and the prognosis following radical operation. For example, D. H. Patey and R. W. Scarff[2] divide 50 cases of cancer of the breast, operated upon five or more years ago, into three histological types, and on analysing the ultimate results find, as might be expected, that the prognosis in the less malignant types is very much more favourable than in the others. They also note that there is a preponderance of the more benign types of growth in the early cases, showing that the favourable stage lasts longer in cases of this type. A parallel investigation of carcinoma of the cervix treated by radium at the Memorial Hospital, New York, has been described by W. P. Healy.[3] He has taken for investigation a block of 200 cases treated in 1922 and 1923, and he, too, divides his cases into three groups, which he calls the adult, the plexiform, and the anaplastic. During the period under review 25 advanced cases of the adult or least malignant group were treated, and only one of these patients was well after four and five years (4 per cent.). In the anaplastic or most malignant group there were 14 survivals out of 33 cases treated (42 per cent.). This is in striking contrast both to Patey and Scarff's results with the operative treatment of carcinoma of the breast, and with other studies on the operative treatment of carcinoma of the cervix, which all show that the best results are obtained when the growth is of the adult type. Thus at the Johns Hopkins Hospital 47 per cent. of cases of the adult type survived and only 9·5 per cent. of the anaplastic type. The figures from the Mayo Clinic are similar—namely, 53 and 9·5 per cent. Healy finds that in operable cases the prognosis for cases treated by radium varies little with the histological characteristics. If his findings with the inoperable cases truly represent the response of particular types of growth to irradiation, this lack of differentiation can probably be explained by the early lymphatic spread of more rapidly growing types of growth. When compared with the results of operation his figures are still very striking, and, on the whole, it is evident that the factors which influence prognosis are quite different in the two main methods of treating cancer. Whereas with surgery the outlook is better the more stable the type of growth, with irradiation it is the unstable, atypical, and more rapidly growing neoplasm which reacts to treatment.

THE INDIAN MEDICAL YEAR.

YEAR by year Lieut.-Colonel R. Knowles, I.M.S., of the Calcutta School of Tropical Medicine, with the assistance of collaborators in various provinces, edits a review of medicine, surgery, and public health in India, which is published as a supplement to the *Indian Medical Gazette*. The 1927 review contains 48 pages, of which the greater part is devoted to questions of public health and research. It may be assumed that the comparative neglect of clinical medicine is not the editor's fault, but is due to the fact that practising physicians and surgeons in India are busy men who do not readily commit their work to writing. The period under review includes the meetings of the Congress of the Far Eastern Association of Tropical Medicine in Calcutta which added so greatly to the interest of the year. Sir Ronald Ross's tour in Malaya and Assam afforded a much-needed stimulus to antimalarial work. The fact that it is the commercial interests that are setting the lead to-day in the control of malaria lends point to Sir Ronald's contention that a large-scale official campaign would soon justify the necessary outlay. The situation is not without its humorous side, for at the Presidency General Hospital in Calcutta, where much of his work was done, both he and the guests assembled in his honour were ferociously attacked by mosquitoes. In spite, however, of slow progress in some directions, a serious effort is really being made in many places to cope with malaria, and the necessary knowledge is being steadily accumulated. A malaria survey of the tea gardens of Assam has been completed, and much labour is being wisely expended in studying the anopheline mosquitoes, particularly with regard to their habits and environment.

At the Haffkine Institute in Bombay efforts are being directed towards producing a potent serum for the treatment of plague and improving the present prophylactic vaccine. Cholera has also received much attention from various observers, one of whom claims to have established that non-agglutinable can be transformed into agglutinable vibrios under suitable conditions. If this supposition is proved to be correct it may profoundly alter our ideas of immunity in this disease, both during an epidemic and at subsequent reinfections. The old controversy between the supporters of the hypertonic and isotonic saline injection methods of treatment for cholera has again cropped up, and it seems clear that there is a considerable body of clinicians who favour the use of isotonic fluid, combined with adrenalin. The prophylactic value of inoculation on a large scale, in order to lessen the number of carriers, seems to have been proved in Java, and this would certainly deserve attention in India were it not for the religious and other prejudices which stand in the way of compulsory measures of the kind. In dysentery there has been no marked advance to record, unless the claims of d'Herelle with regard to his bacteriophage treatment are supported by further experience. Bacteriophage may also prove a potent remedy for cholera if the hopes of the discoverer are realised. Kala-azar is perhaps the brightest spot in tropical medicine during this period. Both diagnosis and treatment have been revolutionised. The reports on leprosy are encouraging, and it is stated that the results of recent methods of treatment justify the belief that we are now dealing with a curable disease, especially if taken at an early stage. Further work which has been done on epidemic

dropsy appears to point to the rice bacillus, and poisons generated by it in the damaged grain, as the causative agent, but this theory is not yet generally accepted.

The review gives a large amount of detailed information on public health work in the various provinces; the appalling conditions which exist, not only in the smaller communities but also in many considerable towns and cities, are at last attracting more attention. Interest in child welfare and the training of dais or native midwives is extending rapidly, and India is evidently awaking to the facts of maternal and infant mortality, though the process of prevention must be slow. Amongst recent public health advances should be mentioned the campaign against hookworm which is being carried on in the tea and rubber districts of the Southern Presidency. It is stated that round-worm infestation is probably of equal or even greater importance in India. In the sphere of medical education the most important event of the year was the second tour of inspection of the principal medical schools by Sir Norman Walker on behalf of the General Medical Council. His friendly if sometimes trenchant criticisms have already borne good fruit.

THE CAUSE OF POMPHOLYX.

WHEN Tilbury Fox first described vesicular eruption in the finger-webs as a clinical entity he regarded it as a retention disorder of the sweat glands. This view has been conclusively disproved, but the name dysidrosis has not been discarded, although pompholyx (blister) is less misleading. The ætiology of these common affections is still in dispute, and there is some evidence that they are increasing in frequency. The Japanese have always held that most if not all, vesicular disorders of this kind on the extremities are due to a mycosis, and the evidence brought forward by Y. Taniguchi [1] for pompholyx of the feet goes far to support this contention, which is also upheld by Jean Darier,[2] who says that a fungus can be recovered in no less than 80 per cent. "des cas presentant l'aspect de la dysidrose." Taniguchi does not concern himself in this study with the palmar cases, which he admits need further investigation, but in the 50 cases of plantar pompholyx examined he never once failed to recover fungi which in their cultural features closely resemble the group described by Sabouraud as *Trichophyton radiolatum*. He did not content himself with histological demonstration and cultural recovery of the pure mycelium; he went a step further and inoculated it into five persons who submitted the skin of their feet to the experiment, and he succeeded in accurately reproducing the typical clinical manifestations of itching and vesiculation, the organism being again recovered in each case. He claims that as far as the feet are concerned his experiments seem to rule out the existence of an "idiopathic dysidrosis." He evidently believes that the same conclusion will eventually be reached as regards the hands, and points out that *Epidermophyton inguinale* was isolated in five out of 13 cases of interdigital eczema examined in the course of his experiments.

THE TECHNIQUE OF PROSTATECTOMY.

JUDGING from reports [3] of the fortieth annual meeting of the American Association of Genito-Urinary Surgeons the ideal technique of prostatectomy seems to be as much in doubt on the other side of the Atlantic as it is here. Not only are urologists divided into two fairly distinct schools, according to their preference for the perineal and the suprapubic route, but within these schools there are many different opinions as to how the operation should be done. Especially noticeable were these differences of opinion in the discussions on post-operative hæmorrhage, which showed that there are those who pin their faith to suture as a means of dealing with bleeding, and an equally large number who rely on packing or on some form of hæmostatic bag. W. E. Lower, who belongs to the suture school, is so confident of his methods that he is prepared as a rule to dispense with drainage and to close the bladder. C. H. Chetwood, who follows Lower's method of suture, has not gone so far as this and uses a small drainage-tube. Greater unanimity was shown on the subject of local anæsthesia. Edwin Davis reported 176 consecutive cases of perineal prostatectomy operated on under sacral anæsthesia, with excellent results. H. G. Hamer, on the other hand, prefers local anæsthesia. He is a partisan of the suprapubic route, approaching the bladder through a median incision previously infiltrated from the pubes to the umbilicus with Schlesich's solution. In the discussion on Davis's paper, Hugh Young raised the objection that sacral anæsthesia is difficult to induce, requires special training, and is liable to consume a great deal of time. He himself had found that caudal anæsthesia was usually sufficient and that it was unnecessary to make the lateral injections into the nerves as they emerged from the canals in the sacrum in order to get excellent anæsthesia for perineal prostatectomy. At first, he said, he had employed 50 c.cm. of a 1 per cent. solution, but with this technique there had often been a rapid and pronounced drop in blood pressure owing to the drug penetrating to the dorsal region. He had, therefore, substituted a 3 per cent. solution of which he injected only 20 c.cm. With this technique an equally satisfactory anæsthesia was obtained without the drop in blood pressure. In only 5 to 8 per cent. of cases had it been necessary to supplement this with a small amount of gas and oxygen.

THE EARLY VICISSITUDES OF QUININE

FEW remedies are in such universal demand as quinine, and few have passed through such difficult times before their value became established. The drug must have been used by natives from time immemorial, and there are many traditions of its origin. An unlikely one is that an earthquake precipitated some trees into a pool, where they rotted and infused the water with their bitter essence; a fever-stricken Indian chancing to drink the water was miraculously cured. This may have happened, but even if the Indian had connected his experience with the trees—a feat quite beyond most minds at his stage of development—it would have taken the tribe hundreds of years to improve on the method of throwing trees into a lake to rot, and the story goes that the use of the crushed bark sprang into prompt acceptance. Another suggestion is that the natives imitate the local carnivora, which are said to gnaw the bark of the tree when they feel ill, somewhat as dogs eat grass. Dr. S. Abbatucci,[1] summarising a recent lecture by Dr. Alessandro Canezza, director of the Lancisian Library at Rome, agrees with the legend that the first person to import quinine into Europe was the Countess de Chinchon, wife of the Spanish Viceroy of Peru. This seems a more probable derivation than the alleged Inca expression "china-china" (food), suggested by one authority. The Jesuit missionaries, who had known it for some time, treated her with it for malaria, and she was so impressed that when she and her husband went back to Spain in 1639 they took a supply with them and distributed it broadcast under the name of Jesuit's powder. A few years later a superior of the Order of St. Ignatius de Loyola, Father Bartholomew Tafur, employed it with success on Louis XIV. when he was Dauphin, and its renown spread into Belgium and England. In this country, however, where Protestant fervour was at boiling-point, the drug was anathematised as an invention of the Devil. Lively controversy about its value soon took place on the Continent. The Governor of Belgium, Leopold

[1] Revue de Méd., 1928, No. 4, 563.

William of Austria, had been treated with quinine for a tertian fever; he had a relapse and his physician, Chifflet, advised him not to continue the treatment. The ingenious Chifflet held the new remedy responsible for his death, and inveighed against its uncertainty and dangers in a pamphlet. H. Fabri, director of the penitentiary of St. Peter at Rome, replied, after the manner of the age, at great length and with some acerbity. Others took up this leisurely duel, which lasted long after Chifflet's death in 1671 had spared him the mortification of seeing the success of quinine. One of its most ardent supporters during this warfare was the Cardinal of Lugo, whose energetic championship gave it the alternative name of Cardinal's powder. The Roman College of Jesuits which, like most religious houses of note, had its own dispensary, was the chief centre of distribution for the drug. In the sanctuary of the Hospital of the Holy Ghost there appears a series of artistic frescoes in which the Cardinal is depicted as distributing quinine to the sick, the Count of Chinchon as receiving it from the Indians, and his lady as taking a therapeutic draught of it. The progress of quinine was hampered by numberless imitations, for it was quite easy to sell large quantities of any root such as valerian, crushed and flavoured with aloes, under the name of cinchona bark. Nevertheless, like most good things, it triumphed in the end, and its struggles have been almost completely forgotten, for few medical men, except those especially concerned with the history of medicine, have ever heard of pulvis patrum, remedium anglicum, or Jesuit's powder.

THE LATE CONSTANTINOPLE BOARD OF HEALTH.

THE internationalisation of preventive medicine has made remarkably rapid progress in the last two decades. The first impetus was given to the process by the establishment, as the result of the Rome Arrangement of 1907, of the International Health Office, with seat in Paris. This was followed, some 12 years later, by the creation of the Health Organisation of the League of Nations, which, while leaving the powers and functions of the Paris Office largely untouched, absorbed it into itself, as the General Advisory Health Council of the League. With these bodies the future of the international control of disease mainly lies. In the past, before this process of centralisation had been carried out, such international control was more or less limited, geographically and otherwise, to the efforts of the four International Boards of Health to prevent the infection of cholera, plague, and other diseases from invading Europe from the Eastern countries, where they are more or less constantly present. Those Boards—of Alexandria, Tehran, Tangier, and Constantinople—came into being at different dates in the last century; their existence was recognised and their mandates more or less clearly defined by the successive International Sanitary Conferences—from the first one in 1851 down to the latest, that of 1926. The Alexandria Board continues to function, and now plays the principal part in maintaining the sanitary barrier between the East and Europe; its powers were considerably enhanced and extended by the International Sanitary Convention of 1926. The Tehran Board also continues to exist; its powers and its mandate have always been more limited than those of the Alexandria or the Constantinople Boards, as readers of THE LANCET will have gathered from the interesting articles from the pen of Dr. A. R. Neligan, the British delegate to the Board, which appeared in our columns in 1926. The Tangier Board has never possessed the importance or powers of the other three Boards; as a result of recent political changes in Morocco the area of its labours is now limited to the small internationalised zone of Tangier and the immediately adjoining territory. Finally, the Constantinople Board has ceased to exist, and a purely Turkish administration is now charged with the sanitary defences of the greatly diminished Turkish coasts and frontiers. In 1923 we published a series of articles relating the history of that Board, written by Dr. F. G. Clemow, who was for so many years the British delegate to that body. To-day we publish a "Supplementary Note" by the same author, throwing further light on the origin of the Board and on many points connected with its history. It should be counted to the Turks for righteousness that, years before the Constantinople Board existed, they themselves conceived the grandiose scheme of a great lazaret on the Bosphorus, with a central sanitary board and health offices in the principal Turkish ports; and that, as far back as 1837, they put forward proposals that clearly foreshadowed the modern practice of "surveillance"—as distinct from "observation"—as a defensive measure against the spread of plague. Though admittedly a "footnote to history," the article, as such "footnotes" frequently are, is illuminating on many matters of interest, from the extraordinary fanaticism of certain races in the presence of disease to the process, only briefly mentioned, of liquidating a long-established and complex body like the Constantinople Board of Health and the organisation it administered.

EXTIRPATION OF THE GALL-BLADDER.

A STUDY of the literature of surgical treatment of gall-stones reveals a difference of opinion between those who regard cholecystectomy as an operation of unconditional choice and those who defend the efficacy of cholecystotomy. Direct investigations intended to define the intimate function of the gall-bladder seem to have been somewhat neglected so that we have no exact criteria of the effect of its ablation, many surgeons speaking of cholecystectomy as they would of an operation to remove a useless appendix. Such a view is opposed by Prof. G. Balice,[1] of the University of Naples, who is convinced that the gall-bladder has a physiological importance far beyond that of a mere receptacle or reservoir, though he admits that its extirpation is not harmful to the organic economy except indirectly and by the possible consequences of an exuberance of intestinal flora due to an absence of inhibition by the cystic bile. Some authorities, he says, think it necessary to take away the gall-bladder to prevent the formation of calculi, but this theory must be accepted with reserve since calculosis has been observed after cholecystectomy with or without reformation of a biliary vesicle from the stump of the cystic duct—not to mention those cases in which there is calculosis of the bile-ducts with congenital absence of the gall-bladder. He considers it justifiable to extirpate the gall-bladder to avoid the dangers of a subsequent cholecystitis, but maintains that such intervention cannot be justified on the mere suspicion, for instance, that typhoid bacilli are lodged there. Mayo Robson is quoted as holding that cholecystectomy is unnecessary in ordinary cholelithiasis when the gall-bladder is not seriously damaged and the cystic duct neither ulcerated nor constricted; Robson's statistics in 1917 showed 53 per cent. of complete recoveries after cystotomy and 71 per cent. after cystectomy. Some surgeons, Prof. Balice continues, have always been in favour of cholecystotomy, and Harris Brownlee maintains that the gall-bladder acts as a safety-valve for the liver, and cites cases in which recovery was impossible as it was found to be atrophied and empty. From his study of reported cases of operation on the biliary passages Balice has come to the conclusion that more attention has been paid to the anatomical and surgical problem than to estimating the physiological importance of the organ extirpated, and that researches have been directed more to attaining surgical perfection in the different modes of intervention than to estimating the disequilibrium caused by loss of the gall-bladder. Whilst agreeing that it should be

[1] Policlinico (Surgical Section), Nov. 15th, 1928.

removed whenever there is reason to fear that its presence would entail worse evils, he believes that it should otherwise be preserved. It is only by such action, he remarks, that the surgeon will show that beyond a passion for operation he has a scientific culture which guides him in interpreting the phenomena he is called upon to treat.

Considerable sympathy will be felt with Prof. Balice's views; at the same time we have clinical evidence from thousands of cases that cholecystectomy is very often harmless—that human beings can get on well without a gall-bladder. There is also evidence that a compensatory mechanism is set up after cholecystectomy. Beale in 1889 first described small parietal saccules, in the walls of the bile-ducts, which apparently have a similar function to the gall-bladder. These saccules are strongly developed in animals, such as the horse, in whom this organ is absent, and in his Mütter lecture to the Royal College of Physicians at Philadelphia in 1923 J. E. Sweet described how, after cholecystectomy in dogs, the parietal saccules grow out and branch and seem to take on the function of the gall-bladder which has been removed.

THE INDUSTRIAL HEALTH EDUCATION SOCIETY.

A MEMORANDUM has been circulated by this Society setting out its objects and affirming the need for health propaganda among workers, both in order to mitigate sickness and disease of an occupational nature and to instil sound teaching on matters of health generally. The need for such health propaganda was shown in a recent report of Sir George Newman, wherein it was stated that in 1927 30½ million weeks' work was lost through sickness and disablement among insured workers alone, while £30,000,000 was spent in sickness benefit and medical treatment among these same persons. For three years the Society, getting the services of doctors free, was able to organise health-talks of pertinent interest to every class of worker; but the fees and out-of-pocket expenses and the supplying of medical literature, often costly, in order that the lecturers might speak from the latest information has depleted the available funds, and this at a time when success has stimulated the Society to extend its operations. In 1927 the income was £2254, while it is now estimated that if the large and growing demands for the services offered are to be met the annual expenditure will have to be at least £5000. A confident eye, however, is turned towards the various employers' organisations, individual firms, and trades-unions for generous support. All will agree with the Society in feeling that the healthier the workers are the better will production be, with benefit alike to employers and employed, so that the Industrial Health Education Society has no difficulty in making out a strong claim for support. The hon. President of the Society is Sir Humphry Rolleston, the general secretary Mr. James Mackenzie, and the address 84, Kingsway, W.C.

Lady Singer has given £500 to the Royal Society of Medicine in memory of the late Sir David Ferrier, F.R.S., with whose work she was associated for some years. The money is to be invested and the income used for the purchase of neurological works for the library. Each book so purchased will bear a memorial bookplate.

Prof. J. H. Zaaijer, of the University of Leyden, will deliver the Hunterian lecture of the Hunterian Society at 9 P.M. on Monday next at the Mansion House, London. His subject will be the Surgery of the Œsophagus and Lungs. It is announced that the Society's annual dinner will be held on Thursday, Feb. 14th, at the May Fair Hotel, Berkeley-square, W.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XVIII.—THE INTERPRETATION OF THE WASSERMANN REACTION IN CHILDREN.

Taking of the Blood from Children for the Test.

IF the Wassermann reaction alone is to be tested 1 c.cm. or even less of blood will suffice, but if it be thought desirable to carry out in addition any of the "flocculation" tests, which will be referred to later, 3 or 5 c.cm. of blood will be necessary. Although in hospital practice and to a skilled pathologist with adequate assistance the taking of blood, even from the youngest infant, rarely presents any difficulty, it is usually inadvisable for various reasons for the practitioner to take the blood himself; it is wiser to allow a pathologist to do so.

The first essential is to have a good syringe, and this should be an all-glass syringe and not a "Record" glass and metal syringe, for with the latter the piston is apt to move stiffly. For many years I have used the three-piece all-glass "Agla" syringes made by Burroughs Wellcome and Co., which are very smooth in action. A 1 c.cm., 3 c.cm., or 5 c.cm. syringe may be used according to the amount of blood required, which is best obtained by vein puncture. From infants under 12 months in whom the anterior fontanelle is still open. the blood can be obtained quite easily from the longitudinal sinus by puncturing the fontanelle at its posterior angle. I have obtained blood from infants in this manner many hundreds of times, usually without any difficulty (except in cases of marked hydrocephalus when the landmarks are apt to be wanting), and with no ill-effects to the patients, and once the initial diffidence has been overcome this method of obtaining blood from infants will always be adopted. Other veins which are also selected for puncture are the anterior cubital vein, such as is used in adults, the external jugular vein, and one of the scalp veins. If no syringe is available, or if for any reason it be thought undesirable to puncture a vein, sufficient blood for the Wassermann test (½–1 c.cm.) may sometimes be obtained by puncturing the heel, big toe, or possibly the thumb or ear with a needle or glass pricker, but personally I never use or recommend this method, as it is more irksome to the patient, takes longer, and very often fails. The syringe used should either be dry sterilised or have been boiled in water and then washed through with normal saline, by aspirating this through the needle and then emptying the syringe. On no account should ether, alcohol, or methylated spirit or other antiseptic be present in the needle or syringe, because the admixture of any of these with the blood spoils the blood for the test. If the syringe, after having been boiled, is not washed out with saline, the small amount of water left in the syringe leads to hæmolysis of the blood. When the requisite amount of blood has been obtained in the syringe the needle is withdrawn and a small pad of gauze or cotton-wool held on the puncture hole by the assistant, while the blood is pushed out into the tube in which it is to be sent to the pathologist. The blood should not be allowed to remain any appreciable time in the syringe; otherwise it may begin to clot and the piston will stick.

For practical and working purposes we may take it that, in this country and elsewhere outside the tropics, a *strongly positive* Wassermann reaction indicates syphilis. On the other hand, a negative Wassermann reaction does not necessarily contra-indicate syphilis, though it may be correct in 90 per cent. of the cases.

Technique.

Without going into details of technique, we may recall the fact that some sera in the appropriate dilution, and in the presence of the appropriate antigen, are able to "fix" three minimal hæmolytic doses or units of complement; others can fix 5 units and are then said to have a stronger W.R. than the former; others, again, may fix the 5 units of complement with only half, one-quarter, one-eighth, or even less of the standard quantity of serum; such sera

would be regarded as having progressively stronger Wassermann reactions. The "indicator" which is used to show the presence or absence of unfixed complement is called a "hæmolytic system," and consists of a standard mixture of an emulsion of sheep's red cells and sheep's-cell hæmolytic serum, which has been heated to destroy its natural complement.

After preliminary titration of all the reagents, the first stage of the actual test consists of mixing together definite amounts of: (1) the patient's serum, previously heated to destroy its natural complement; (2) dilution of antigen extract, and (3) complement in guinea-pig's serum (3 and/or 5 units). The whole is made up to a definite volume and kept for half an hour at room temperature and then for half an hour in the water-bath at 37·5° C.

In the second stage equal volumes of the "hæmolytic system" are added to every tube, and after vigorous shaking the whole is incubated at 37·5° and examined after 5, 10, and 15 minutes, and read at the end of half an hour. If the corpuscles are completely dissolved and hæmolysed it is because the complement at the end of stage 1 has been free and not mixed, and such a reaction is called a (clear) negative. If the corpuscles are not completely dissolved after the water-bath the tubes should be kept overnight in the ice-chest to allow the corpuscles to subside and the next morning the reaction can be read off and the relative amount of residual corpuscles estimated.

The Report.

If the supernatant liquid is quite colourless it is obvious that none of the sheep's cells has been dissolved; in others words, the whole of the complement added in stage 1 has been fixed and the reaction is called a positive one, expressing the complete absence of hæmolysis by the figure 4. If half the corpuscles are hæmolysed the figure 2 is used, if less than half the figure 3, and if more than half the figure 1, so that for any one tube of the test one of the figures 4, 3, 2, 1, or 0 could be used to represent the result of the test in that tube.

In cases which are likely to be syphilitic, as well as in those which are known to be syphilitic and are undergoing treatment, it is advisable to use two different strengths of serum and also 3 and 5 units of complement for the Wassermann test. If such a serum were very strongly positive there would be no hæmolysis in any of the test-tubes and the result would be expressed by the figures 4, 4, 4, 4; if the blood were less strongly positive and there was complete hæmolysis with the smaller volume of serum (1 in 30 dilution) and 5 units of complement the reading of the result would be 4, 4, 4, 0.* A blood giving a reading of, say, 3, 2, 1, 1 would be regarded as a weak or partial positive.

Other Methods of Reporting on the Wassermann Reaction.

The method of reporting on the Wassermann reaction which has just been described is one which I have used for many years and which is also adopted by some other pathologists. It must be pointed out, however, that some years ago the Ministry of Health suggested a somewhat different notation for Wassermann reports, the symbols recommended being ++, +, ±, and −.

Thus ++ signifies a strongly positive Wassermann reaction, or a sigma test (vide infra), giving more than 3·9 units in 20 hours. This corresponds to the ++++ of some pathologists and to my 4, 4, 4, 4; + means a positive Wassermann reaction with fixation of the standard amount of complement, or a sigma test giving 1·5 to 3·9 units in 20 hours. This corresponds to the ++ of some pathologists and to my 4, 4, 0, 0; ± means a doubtful Wassermann reaction, with some hæmolysis in the standard tube, or a sigma test giving 1 to 1·4 units in 20 hours. Some pathologists would express this as ± ±, and with my notation it would be 2, 1, 0, 0; − signifies a negative Wassermann reaction or a sigma test giving less than 1 unit in 20 hours.

Formerly practically every pathologist had his own method of performing the Wassermann test, though the underlying principles were the same in most methods. In a test requiring the use of so many reagents of a "biological" nature, it followed that unless a more or less standardised method of titrating the reagents were employed, and further, that such standardised reagents were used in a prescribed manner, the results obtained by different pathologists would hardly be comparable. In consequence, the subject of the technique of the Wassermann reaction was fully considered by a Committee of the Medical Research Council some years ago with the result that four approved methods of performing the test were decided upon, and one or other of these methods is now used in most laboratories in this country. Even so, and using the greatest care in standardising the reagents and in carrying out the test and controls, an experienced worker may find that one week the results may tend to come out rather on the positive side, another week rather on the negative side. This is hardly to be wondered at in view of the complicated nature of the reagents employed and the fact that the actual mechanism of interaction of these reagents is so little understood.

The Sigma and Kahn Reactions.

It was on account of these admittedly inherent and unexplained difficulties in the actual performance of the Wassermann tests that simpler tests for the detection of syphilis were sought and elaborated. As a result (1) the "flocculation" test of Sachs-Georgi, modified by Dreyer and Ward and called by them the "sigma" reaction; (2) the Kahn; (3) the Meinicke; and (4) the Vernes flocculation or precipitation tests were introduced. The principle underlying all these tests is the addition of a specially prepared antigen to the patient's serum; in the case of a syphilitic serum a coarse flocculation or precipitate is produced, whereas in a normal serum no such phenomenon is observed. The advantages of these tests are: (1) that only one reagent, the antigen, is required; (2) the test is easily carried out; (3) the results are quantitative; and (4) in treated cases these tests are more sensitive than the Wassermann reaction, for they may remain positive long after the Wassermann reaction has become negative, which may be an indication that further treatment of the patient is desirable to prevent a relapse.

In reporting upon the "sigma" reaction any result above 1·5 units at 20–22 hours is regarded as positive; 1·0 to 1·5 units at 20–22 hours is regarded as positive in known cases of syphilis; less than 1·0 unit at 20–22 hours is regarded as negative, but the incubation is continued 40–44 hours, and if more than 1 unit at the end of that period is regarded as positive in known cases of syphilis only.

The Significance of a Positive Reaction in Children.

In children, as in adults, the Wassermann reaction may be strongly positive (4, 4, 4, 4), positive (4, 3, 1, 0), weakly positive (3, 2, 1, 0), or negative (0, 0, 0, 0), and it will be advisable to consider the significance of these results at different age-periods. A strongly positive or positive Wassermann reaction in a child of any age indicates syphilis and the necessity for treatment, with the possible exception of an apparently healthy new-born child or an infant a few weeks old, whose syphilitic mother has a positive Wassermann reaction. It is stated by some authorities that the Wassermann substance may pass from mother to child so that the latter reacts positively for some weeks, and that afterwards if the child is healthy the reaction becomes and remains negative. Other authorities maintain that the Wassermann substance is unable to traverse the placenta and that a positive reaction in a child is an indication of a syphilitic infection in the child. Of course, if an infant at birth or shortly afterwards has snuffles or a rash, particularly of a vesicular or bullous character, and if its Wassermann reaction is positive, it certainly has syphilis and should be treated accordingly. It is advisable to obtain confirmatory

* I have elsewhere (THE LANCET, 1927, ii., 692; Brit. Jour. of Venereal Dis.) described in detail my nomenclature for reporting on the Wassermann reaction in blood and cerebro-spinal fluid.

evidence by examining the mother's blood, and—unless the infection is of long standing in the mother—one usually finds that her reaction is also positive.

When the children in a family in which a frank case of inherited syphilis has been detected are systematically examined one or more may be found with a positive Wassermann reaction, but with no symptoms or signs, except perhaps suggestive teeth. Such cases are to be regarded as latent inherited syphilitics and most, if not all, syphilologists recommend treatment to guard against the possibility of later manifestations of the inherited disease. My own practice for several years has been to treat these children with injections of arsenicals and with mercury iodide or bismuth preparations until the Wassermann reaction becomes negative and remains so. Hitherto I have not seen such a case relapse or develop signs of syphilis.

A Negative Wassermann Reaction.

A negative Wassermann reaction is not conclusive evidence against syphilis, though a repeated negative is probably correct in 90 per cent. of cases. It is well known, of course, that infants who are found to have obvious signs of inherited syphilis at the age of 2 or 3 months may have been quite healthy at birth and for weeks afterwards. If the blood is tested during the earlier weeks of life—that is, while the disease is incubating—the Wassermann reaction may be found negative, though at the age of 2, 3, or 4 months it may be positive. Cases, however, have been recorded in which the Wassermann reaction was negative, yet the child had obvious symptoms of inherited syphilis. Confirmatory evidence in such cases may be obtained from the examination of the mother's blood. For many years I have made it a practice to test the mother of every suspected child under 1 year, though it should be remembered that if the mother is again pregnant a positive Wassermann reaction may become temporarily negative, and the result therefore unreliable. If an infant has obvious clinical syphilis it should be treated for the disease *even though its Wassermann reaction is negative*, and the blood should be tested frequently, for the treatment may for a time provoke a positive reaction (the so-called Herxheimer reaction). Another point which should be borne in mind is that the Wassermann reaction may fluctuate—certainly in treated and probably in untreated cases—so that at one examination it may be negative and when repeated a month or two later it may be strongly positive. Blood tests in doubtful cases should be repeated at intervals of one and two months.

In older children and in young adolescents in whom the infection may be only slight or who may have had mild infantile symptoms and then no sign of the disease for many years the Wassermann reaction may be negative. In such cases the Kahn or other flocculation test may be found positive, and when the patient has been treated or given a "provocative" injection of "914" the Wassermann reaction may become positive.

Weakly Positive Reactions.

It is sometimes stated that in inherited syphilis the Wassermann reaction is nearly always strongly positive, so that a negative or weak reaction may be regarded as evidence against the disease. I believe that to be wrong and I never ignore a weakly positive reaction. In my opinion it is an indication for further investigation in various directions: (1) examination of the patient for signs of the disease; (2) a provocative injection of "914" followed by examination of the blood 2, 7, and 14 days afterwards for the Wassermann and Kahn reactions; (3) investigation of the patient's early history for possible infantile symptoms; (4) inquiries into the mother's obstetric history; and (5) examination of the mother's blood, also that of the patient's brothers and sisters and of their blood reactions. In these various ways I have several times been able to demonstrate that a patient with a weak Wassermann reaction was really syphilitic.

The Wassermann Reaction after Treatment.

In a chronic disease like syphilis it is very difficult to say when a cure has been effected. The disappearance of the symptoms and the general amelioration of the patient's physical condition are important signs of cure, but it may be several years after the cessation of active treatment before one can feel reasonably certain that the patient is cured. Interstitial keratitis is apparently the least amenable to treatment of all the manifestations of inherited syphilis, and I have seen it occur in children who were actually undergoing treatment and on one or two occasions in children who had had several courses of injections and whose Wassermann reaction had already become negative. We see therefore that a negative Wassermann reaction cannot be regarded as conclusive evidence of cure, though the aim of treatment is, in addition to ridding the patient of his syphilitic symptoms, to render the Wassermann reaction permanently negative. For several years I have done the Kahn test in addition to the Wassermann reaction on my treated syphilitic children, and the treatment is continued until the Kahn test as well as the Wassermann reaction is negative. As many as 40 or even 50 injections of arsenic may be required—and one usually finds it is the older children (5 to 10 years of age) who require the longer courses of treatment. As a rule they remain negative, but a small proportion of them relapse serologically, though their general health remains good. A certain proportion of cases—perhaps 10 per cent. of syphilitic children over 1 year of age—remain strongly Wassermann positive even after full courses of treatment, and these comprise cases of congenital neurosyphilis in which the Wassermann reaction in the spinal fluid is found to be strongly positive, cases of ulceration of the palate, naso-pharynx, or larynx, and more rarely cases with periostitis or other manifestation of the inherited disease. The spinal fluid should always be examined in these cases with persistently positive Wassermann reactions, and if it too be found positive malaria therapy should be tried either alone or combined with intrathecal injections of salvarsanised serum, for, so long as the spinal fluid is positive, the possible development of general paralysis or other syphilitic cerebro-spinal disease is not excluded. In the absence of evidence of disease in the central nervous system, and if the patient has had full courses of treatment with arsenic and bismuth and appears well, I have suspended further treatment, and have found that in some cases the Wassermann reaction some years afterwards has become less strongly positive or even negative.

What to Tell the Parents.

Having established the diagnosis of syphilis in mother and child it is in my opinion advisable to be frank with the mother and to tell her that the child is suffering from a "blood" disease which it has inherited from its parents and that a long course of treatment is necessary in the interest of the child's future health and well-being. If any apathy or even antagonism is manifested by the parents one can point out that the child is the innocent victim of disease in its forbears and that it is the duty of its parents to see that it receives proper treatment *at once*, as an insurance against possible future disablement. The parents should also be advised to undergo treatment to avoid the risk of a future breakdown in health which may render one or both of them unfit to provide for their children. I have come across at least a dozen families in which the syphilitic child has been the third generation to suffer from the disease, and from careful investigation in possible third generation cases I conclude that such instances may be more numerous than is generally believed. When a mother asks me how her child can have contracted the disease I tell her that it is quite possible for her to have inherited the disease herself and to have passed it on to her child; also, that the husband may be quite free from infection, and under the existing conditions he cannot be infected by his wife. Even

when I disclose the actual nature of the disease to the parents—as it is sometimes necessary to do to induce them to bring the child for treatment or to continue to do so, in case of their default—I have never had any domestic difficulties when I have explained how one or other parent may have inherited the disease from the child's grandparents and passed it on to the child.

In view of the fact that the treatment and subsequent supervision of the patient is likely to be very prolonged—extending, as it should, over many years—and that the parents' willing coöperation is necessary, one should always be conciliatory and sympathetic with the parents, yet sufficiently firm when they fail to bring the child for treatment to make them realise their responsibility for its present and future welfare.

Special Articles.

THE LATE CONSTANTINOPLE BOARD OF HEALTH.

A SUPPLEMENTARY NOTE.

BY F. G. CLEMOW, C.M.G., M.D., D.P.H.,
FORMER BRITISH DELEGATE TO THE BOARD.

IN three earlier papers that appeared in the columns of THE LANCET in the summer of 1923[1] I gave a short account of the origin and history of the late Constantinople Board of Health. In the interval that has since elapsed further research into the surviving records of the time—notably the *procès verbaux* and other archives of the Board itself and the official correspondence relating to matters dealt with by the Board—has thrown much fresh light on the subject; and the new material thus acquired appears to be of such interest that I may perhaps be permitted to supplement those articles by some additional notes; to correct one erroneous statement; and to relate, quite briefly, how the affairs of the Board have been finally wound up and disposed of.

It was stated in the opening paper that, while 1839 had not infrequently been given as the date of the Board's coming into existence, some form of mixed Sanitary Council was unquestionably sitting in Constantinople at least as early as 1838, while the Turks themselves claim that, on the occasion of the great cholera epidemic of 1819, some kind of quarantine was applied to ships arriving in the Bosphorus, and that in 1836 a Turkish Quarantine Board, composed of three members, was already in existence. It has not proved possible to find positive confirmation of this latter statement, but it is quite possible that the Turkish claim is a just one, for already some years before that date there had been a moving of the waters in Turkey in the matter of protective quarantines. It was an era of great reforms in that country. The reigning Sultan, Mahmud II, had done more than any of his predecessors to abolish abuses, encourage progress, and introduce into a backward country the ways and methods of western civilisation. He had destroyed the Janissaries in 1826; he entirely reorganised the military and financial administrations; he suppressed those tyrannous local hereditary chiefs, known as the Deré Beys; and brought about many other reforms. And now he was desirous that Turkey, which was so specially liable to the ravages of plague and other pestilential diseases, should adopt those measures of protection that had long been practised by other and more advanced countries. His efforts to attain this end, however, met with no little opposition—both from his own people, whose fatalistic outlook on life could see in such measures nothing but a flouting of the Divine will, and from the foreign nations, who feared that those same measures, as applied in Turkey, would mean nothing but disastrous delays, cost and vexation for their shipping and commerce. But the Sultan was determined to overcome all such obstacles, and the successive steps in the process are of sufficient interest to be told in some detail.

As early as 1831 a request was addressed to the British Ambassador, asking him to procure "a plan of a lazaretto, to be established in Turkey, on European principles." Writing a few years later,[2] the Chaplain to the Embassy says:—

"The next conquest over religious prejudices was taking precautions against the plague. They had carried conviction of its sinfulness to such an extent that, in the year 1812, when the disorder ravaged the city [of Constantinople], they would not suffer prayers to be offered up in the mosques to stay it, till 1000 persons were carried daily out of the Top Kapousi Gate to be buried, deeming even that a murmuring against Providence and a want of due submission to its decrees.[3] But after the late Russian campaign they began seriously to consider the absurdity of those opinions, and attend to the regulations enjoined by the Sultan. An energetic pasha, seeing the plague break out in his district, drew a cordon round a village where it was reigning, and suffered no one to pass in or out of it on any pretence. After some time everything was silent, and on examination it was found that the whole population was dead in their houses, but the disease never extended beyond the spot where this frightful precautionary sacrifice was made.

"Availing himself of the impression which these and similar occurrences had made on the people, the Sultan caused application to be made to the British Minister at Constantinople for a plan of a lazaretto to be established in Turkey on European principles, with a view to prevent the introduction of the disease. This application was despatched to England, and orders were sent to Malta that a plan of the lazaretto of that place should be forwarded to the Turkish Government. This institution, however, was liable to many objections. It had been erected by the knights at a time when the island had no commerce, and when the thing was imperfectly understood, so it was determined to draw up a plan on the most improved system, in which all that was excellent should be embodied. The direction of the whole was given to Captain Schembri, a native of Malta, who had been particularly active and efficient when the plague had ravaged the island in 1813 and had continued to superintend the quarantine for 20 years since that period. With this intelligent man and on his benevolent mission I sailed," continues the Chaplain, "from Malta and we arrived at Pera on May 1st, 1831. His plan was submitted to the Sultan and highly approved of. It embraced the establishment of quarantine offices and lazarettos on the Dardanelles and Bosphorus, and all the towns on the coasts of Asia and Europe, with a board of health to organise a sanatory police, to watch the introduction and appearance of the disease, and take immediate precautions. The lazaret to be built for the capital is intended to be a noble edifice, 700 feet in length, in an airy and pleasant situation on the shores of the Bosphorus, and on such a plan that it will present to the view an elegant and cheerful abode, calculated rather to inspire pleasing thoughts than those dismal and depressing reflections, excited by other gloomy lazarettos, which, by sinking the mind, predispose the body to any complaint. The expense of the establishment is estimated at £20,000. When this is finished it will probably be the completest institution of the kind that ever was in the world, and it is not impossible that European nations may hereafter adopt this quarantine establishment of the Sultan for their model, and so take their plans for the future prevention of the plague from a people who for centuries obstinately persisted in allowing no precautions to be taken. The value of this important innovation will be appreciated, by considering that the European nations have drawn a vast cordon of perhaps 10,000 miles by sea and land round the Turkish Empire, forming a barrier through which no one is allowed immediately to pass, under penalty

[1] THE LANCET, 1923, i., 1074, 1126, and 1180.

[2] A Residence at Constantinople. By the Rev. R. Walsh, LL.D. London, 1836. Vol. II., Chap. XI.

[3] Such fatalism was not confined to Turks, nor to Moslems. Dr. Grassi, of Alexandria, wrote in 1839 of the "fanaticism of the Abyssinians (both Moslems and Christians)." They regarded the plague, he says, "as a beneficent emanation of the Divinity, which not only ought not to be avoided, but which every person ought to procure, and fix upon himself, as a means of salvation in a future state." And he relates how, when plague was raging in Jerusalem in 1838, a Copt caught the disease and died. There were 17 Coptic monks in that city—all "threw themselves with eagerness on the death-bed and clothed themselves in the garments of the defunct. All 17 perished."

of death; but when precautions similar to those of Europe are adopted in this country also, the Turks will no longer be an excluded people, but the intercourse will become as free as between one European nation and another, a great obstacle will thus be removed to their amalgamation with us, and they will no longer continue to be a distinct and separate people."

These grandiose conceptions, which even to-day can only be read with admiration, were destined to be but partially realised. The great lazaret on the Bosphorus, that was to be a model to other nations, remained a dream of Alnaschar. But the "board of health," the quarantine offices and lazarets around the coasts of Asiatic and European Turkey did in time come into existence. The Board of Health, indeed, was formed at the latest some seven years after these great reforms were foreshadowed, and, as was stated above, it is quite possible that some sort of board may have already existed, as the Turks claim, as early as 1836.

Early Projects for Quarantine.

A year earlier it would appear that, whether there was then any central quarantine authority or not, local authorities were already, on their own initiative, arranging to set up quarantine in their districts, with the agreement and coöperation of the foreign consular representatives. Thus, on Dec. 19th, 1835, the Governor of Prévesa, Saly Agha, came to an agreement with the British, French, and Greek consuls for the adoption of a set of quarantine regulations to be applied in that port. Under these rules a remarkable degree of power was given to the three consuls named. All ships of the nations they represented, coming from a plague-infected or plague-suspected place, were to submit to such precautions as might from time to time be decreed by the three consuls. Ships of any other Power were to put themselves either under the protection of one of the consuls or under the jurisdiction of the Customs authorities, who "shall be held to conform strictly to the orders" issued by the consuls. Penalties were to be imposed on persons breaking the rules, and the "Primate of Prévesa" was to nominate four health officers, "who shall be required, on entering upon their functions, to make oath for the due performance of the same." Their pay was the princely sum of six piastres (1*s.*) a day—this and their maintenance to be at the charge of the ship.

In like manner we find that, in September, 1837, the consuls of the chief European Powers at the Dardanelles were invited to meet the Pasha-Governor to discuss the best method of carrying out the desire of the Sublime Porte to establish quarantine in those straits. The proposals put forward by the Pasha, on instructions from the Porte, are of exceptional interest. They were not only remarkably reasonable for the time, but—apart from the quarantine, the duration of which does not appear from the surviving correspondence of the period—were in striking harmony with the principles of present-day practice and of the latest International Sanitary Conventions. Thus it was proposed to put a quarantine upon all ships arriving at the Dardanelles from any place where plague existed; boats were to be sent off to each ship as it arrived, "on the part of the Pasha, as chief of the Quarantine Department, to make inquiry respecting the health of the crew, the particulars of the voyage, and the nature of the cargo, and to demand, if necesary, the ship's papers; also *to note down the names of all the passengers, a list of whom is to be sent to Constantinople.*"[4]

It may reasonably be assumed that the object of this last regulation was to enable the Constantinople authorities to keep the passengers under some form of sanitary or medical supervision after their arrival in that city; and if that assumption is correct, it may be asserted that these Turkish proposals of 1837 clearly foreshadowed the modern practice of "surveillance" (as distinguished from "observation").[5] That practice was first prescribed in an International Sanitary Convention by that of Dresden, 1893, though it had been adopted in England some years before that date.

In spite of their reasonable character, however, the Turkish proposals met with opposition from some of the foreign consuls, and seem to have been dropped. For, writing in November, the British Ambassador in Constantinople states that so far nothing had been done by the Sublime Porte towards setting up the proposed quarantine, adding: "The Ottoman Commissioner who was sent there is dead and no regulations whatever have been made."

In another part of the Turkish realms—the Regency of Tripoli—quarantines and a local Board of Health were already in existence, it would seem, long before 1838. This is shown by a Note addressed by the foreign consuls in Tripoli to the Pasha Governor urging him to establish—

"a well-regulated and efficient quarantine and board of health, upon the same principles which so long existed here and which so effectually preserved the health of the Regency when it was confided to the direction of the Consular corps, with the concurrence of the chief authority of the Regency."[6]

Then, again, we find Prince Metternich, in Austria's reply to the French (unsuccessful) proposal to convoke an International Sanitary Conference in 1838, writing as follows:—

"For the last six years sanitary establishments have existed on the left bank of the Lower Danube, and these have entirely succeeded in preserving Wallachia and Moldavia from the invasion of plague."[7]

It is of interest also to note that the same authority in the same letter, wrote:—

"Lastly, Sultan Mahmoud, who is so disposed to enable the people subject to his sceptre to participate in the benefits of European civilisation, has not only recently manifested, by several publications, his firm determination to introduce quarantine into Turkey, but has even lately applied to us for several persons employed in our Quarantines (who were granted to him immediately)[8] in order that the Commission of Public Health instituted at Constantinople, assisted by their counsels, and by long experience, may be guided in the adoption of sanitary measures."

The "Commission of Public Health instituted at Constantinople" can scarcely have been other than the new Constantinople Board of Health, which was thus clearly in existence as early as 1838. Elsewhere, too, Turkish lazarets were already in being in that year, for on July 11th H.M. Consul in Salonika reported as follows:—

"A spacious building has been engaged for a lazaret for all persons and goods arriving by sea from infected ports, and other lazarets have been established for travellers and merchandise from the interior. Turkish Government tatars and couriers, arriving by steamboat from Constantinople and Smyrna, are put into quarantine, and the dispatches forwarded after fumigation, by other tatars from this."

In October, 1838, moreover, quarantine regulations were already being applied at Trebizond. The British Consul there reported that persons from the interior were subjected to three days' quarantine before being allowed to enter the town, and those who wished to embark on vessels had to do 15 days' quarantine in a lazaret. And in December of the same year a report was received from the British Consul in Candia

[4] Report of Mr. Lander, Consul at the Dardanelles, Sept. 4th, 1837. The italics are not in the original.

[5] The two terms were first clearly defined in a footnote to the Venice Convention of 1897—footnote which, with slight modifications, reappears in the Conventions of Paris (1903) and Paris (1912) in the following form: "The word *observation* signifies: isolation of passengers, either on board a ship or in a lazaret before they obtain free pratique." "The word *surveillance* signifies that the passengers are not isolated, that they obtain free pratique immediately, but they are followed up in the various places to which they are going and subjected there to a medical examination to determine their state of health." This medical visit is repeated daily as long as the "surveillance" lasts.

[6] Correspondence Relating to the Contagion of Plague and the Quarantine Regulations in Foreign Countries, 1836–43. Presented to the House of Commons, 1843.

[7] Ibid.

[8] Among these Austrian advisers was Dr. Minas, who had been head of the Quarantine establishment at Semlin, on the Danube. He arrived in Constantinople in July, 1838. (Proust: "La Défense de l'Euro e contre le Choléra.")

relating to certain proposed alterations in the quarantine law there—expression that implies that some form of quarantine regulations were already in existence.

I should like to take this opportunity to correct one statement that appeared in the earlier articles on this subject. It was there asserted that the Board

"was originally a local body, brought into existence to meet the immediate menace of a plague epidemic, and limiting its aims mainly, if not entirely, to the protection of the Turkish capital. It only later extended its work to the protection of the other ports and frontiers of the Turkish Empire and gradually assumed the many other responsibilities that fell to it during the later decades of its existence."

This, in the light of more recently acquired knowledge, is seen to be erroneous. From the very first the Board did not confine its work to the capital or its neighbourhood, but extended it to other, and far distant, ports and frontiers of the Turkish Empire. Moreover, as has just been shown, in some of the outlying portions of that empire quarantine regulations already existed and were applied even before the Board came into being.

Difficulties with the Sublime Porte.

Reference was made in the earlier articles to a critical moment in the Board's history, when its action met with the disapproval of the reigning Sultan, and

"the latter threatened to swamp it by the nomination of a large number of Turkish members, sufficient to outvote the foreign element on the Board—a threat analogous to that made a few years ago to a more august body in this country."

From the minutes of the Board the following additional details may be gathered. The incident occurred in the summer of 1884. Cholera was prevalent in France, and particularly in Marseilles. The Board had imposed a ten days' quarantine on arrivals in Turkey from French ports. An *iradé* was issued by the Sultan, demanding that some quarantine be also imposed against Varna and other Black Sea ports, on the grounds that passengers might come overland from France to those ports. The Board therefore imposed five days' quarantine and disinfection on arrivals from Varna, Kustenjé, the Danube ports, and Odessa. But even this was not deemed sufficient, and still severer measures were demanded; it would seem also that orders were given, behind the Board's back, to apply such severer measures by the customs and military authorities. The Board protested and refused to recognise these measures or to increase those it had already itself decreed. Thereupon, a fresh *iradé* was issued, nominating seven Turkish doctors as "honorary permanent members" of the Board; these were selected from the highest medical officers in the Turkish civil and military services. The foreign delegates, however, refused to sit with them, and the first and only meeting at which they were—not present, but waiting in rooms adjoining the council chamber—was brought hurriedly to a close. The Board did not meet again for a fortnight (it usually held weekly meetings), and in the interval the matter seems to have been smoothed over for a time and the seven additional members withdrawn.

But a month later, on Sept. 16th, the attack was renewed. The Board had decreed ten days' quarantine against Mediterranean ports and five days against Black Sea ports, on account of the very severe cholera epidemic then raging in Naples. The Porte was again dissatisfied, and the Council of Ministers decided that the Board should be required to discuss the question of increasing the measures jointly with the same seven "honorary members" as before. The decision was further sanctioned by an Imperial *iradé* to the same effect. Once more, however, the foreign delegates protested, and this time, as the minutes show, the Board held no meeting for three weeks; when it met again, the incident had apparently once more been smoothed over and the seven additional members again withdrawn.

The Constantinople Board of Health: Exterior.

The incident well illustrates what was one of the frequent difficulties with which the Board had to contend. When it had first been brought into being, some European Powers were apprehensive lest it should tend to apply over-long quarantines and other excessively restrictive measures, which, it was feared, would only hamper shipping and trade without offering compensating advantages from the public health point of view. These fears, however, had not been realised and, in the majority of instances, the Board's decisions were more or less moderate and in accordance with the professional views current at the time, and were only occasionally reactionary and inspired by the alarm of the moment. But for a great part of its existence, and especially during the long reign of Abdul Hamid, the tendency frequently manifested by the Board—and particularly by the foreign delegates—to rely rather upon modern sanitary measures than upon lengthy quarantines was constantly met by opposition or active interference from the Palace. *Iradé* after *iradé* would be promulgated, demanding longer quarantines or stricter measures than the Board thought necessary to meet a given set of circumstances, and not infrequently a compromise would be arrived at, by the Board decreeing

measures somewhat more severe than those it had already imposed, but somewhat less severe than those demanded by the Palace. As a corollary to this state of affairs, the Board not infrequently decreed in the first instance more stringent measures than it would otherwise have done, in order to forestall Palace interference.

The Final Chapter.

The final chapter in the long history of the Board can be told quite briefly. A short section of the Treaty of Lausanne (1923) dealt with the matter. It was there formally recognised that the Board had ceased to exist as an international body, and the Turkish administration was charged with the sanitary defences of the coasts and frontiers of the greatly diminished Turkish State. It also provided, in the following article, that a Special Commission should meet in Constantinople, in order to liquidate completely all outstanding matters relating to the former organisation :—

Art. 116.—Turkey undertakes to respect to the full the rights of dismissed sanitary employees to an indemnity to be paid out of the funds of the ex-Superior Board of Health of Constantinople, and all other established rights of the employees and ex-employees of that Board and their heirs or representatives ("ayants droit"). All questions relating to those rights, to the destination to be given to the reserve funds of the ex-Superior Board of Health of Constantinople, to the definite liquidation of the former sanitary administration, as also any other similar or connected question, will be settled by a Commission *ad hoc*, composed of one representative of each of the Powers who formerly took part in the Superior Board of Health of Constantinople, with the exception of Germany, Austria, and Hungary. In case of disagreement among the members of this Commission on any question concerning either the above-named liquidation or the affectation of the residue of funds remaining after the liquidation, any Power represented on the Commission will have right to refer the matter to ("d'en saisir") the League of Nations, who will give the final decision.

Other clauses provided that one and the same sanitary tariff must be applied to Turkish and foreign shipping and nationals,[8] and dealt with some other minor matters.

The Liquidation Commission set up by the above article came together in Constantinople in February, 1925, and sat until June, 1926. Its task was one of considerable complexity, and was not rendered easier by the fact that large numbers of the persons to be liquidated were living in distant territories (such as Mesopotamia, Syria, Palestine, Arabia, and so forth) now detached from the former Turkish Empire, or were scattered in different countries of Europe, Africa, Asia, and even America. Its main tasks were to examine the large number (over 500) of claims and requests addressed to it either by former employees or by other persons not connected with the administration ; to compensate former officials and employees for the loss of their posts and the ruin of their careers ; to commute the pensions of sanitary pensioners ; and to dispose of the considerable reserve funds accumulated by the former Board in such a way as to satisfy, so far as might be, the often conflicting claims of the persons just named and those of the Turkish Government and present Turkish sanitary administration.

How far the Commission succeeded in satisfying either those claims or the claims of abstract justice will no doubt always be a matter of difference of opinion among the opposing claimants ; but, as British delegate and secretary-general to the Commission, I am in a position to assert that no effort was spared to arrive at a just and equitable distribution of the large funds that the Commission was called upon to administer, and that, in my opinion, the results arrived at did, on the whole, attain a very high level of justice and equity.

PS.—The accompanying illustration shows the exterior of the Constantinople Board of Health, as it was before the war, and as it still is. It continues to house the (purely Turkish) administration that now looks after the sanitary defences of the diminished Turkish State. The structure itself is of no great age, having been built—or rebuilt—some 30 to 35 years ago, when an earlier edifice had been badly damaged by a severe earthquake. Both buildings were erected over a curious underground, crypt-like structure, of considerable area, which has for long been used as a Moslem mosque. Its history is unknown, but it is believed to have existed from quite early times, possibly dating from the Byzantine era.

[8] The necessity of some such clause had been demonstrated by the fact that, in the autumn of 1922, when Turkey took repossession of the sanitary and other administrations in Constantinople, she at once imposed a preferential sanitary tariff, under which Turkish ships paid two, and foreign ships five, piastres per ton for sanitary dues.

THE HEALTH OF THE SCHOOL-CHILD.

ANNUAL REPORT OF THE CHIEF MEDICAL OFFICER TO THE BOARD OF EDUCATION FOR 1927.[1]

IN his report Sir George Newman points out that about 2,000,000 children are inspected every year, a work which occupies some 2000 doctors, 600 dentists, and nearly 5000 nurses. The first object of the service is the ascertainment and effective treatment of the ailing child and the system involves careful examination of each individual, patient follow-up work, the provision of treatment and after-care, and the adaptation of the educational system to the needs and capacity of the subnormal child.

The figures for 1927 are impressive. Of the 4,967,394 children in average attendance at school 36·7 per cent. were medically examined, an increase of 219·8 on the preceding year. In addition 861,964 were examined as "special cases," bringing the total to 2,685,739, or 54·1 per cent., of the number in average attendance ; 1,719,844 re-examinations were made, an increase of 5 per cent. on the year before. This figure expresses the increasing extent to which school medical officers are criticising the results of treatment to ensure that maximum benefit is obtained. It is recognised that no medical service can be completely adequate unless it provides for continuous medical supervision. Of the 1252 school medical officers, 269 are whole-time, 600 divide their whole time between school and public health work, and 383 are part-time officers ; 449 undertake specialist work ; ophthalmic, aural, anæsthetic, X ray, and orthopædic services occupy 872 part-time and 16 whole-time specialists, and the private practitioner is said to be rendering valuable service. 282 of the school medical officers are women.

Every year about one-fifth of the children examined by routine are found to need some medical treatment, apart from dental disease. Defects of eyesight and enlarged tonsils and adenoids each account for about one-third of the total sum of defects. The number of the children notified in the latter group shows a distinct increase, but otherwise there has been a very slight general decrease in the numbers referred for treatment, and a notable one in the numbers suffering from severe malnutrition. The incidence of defects, other than defective vision, is about 19·5 per cent. in the entrant group and 11 per cent. in the school-leaver group. Some figures, given by the school medical officer for Liverpool, show that the 5-year-old child is approximately half an inch taller and over a pound heavier than he was six years ago, and that the leaver is more than an inch taller and over four pounds heavier than in 1921. Similar figures are recorded from other towns, and the diminished number of children reported as chronically absent from school is another proof of the improving health of the child population. There is also steady progress towards cleanliness ; the numbers of individual

[1] H.M. Stationery Office. 1928. Pp. 204. 1*s.* 6*d.*

children found unclean were: in 1924, 7·4 per cent.; in 1925, 6·5 per cent.; in 1926, 6·4 per cent.; and in 1927, 5·6 per cent.

Development of Treatment Schemes.

It is gratifying to learn that local education authorities are on the whole fully alive to the needs of the children under their control, although financial considerations still hamper the extension of facilities. The most notable advance during 1927 was the extension of orthopædic treatment. New schemes have been approved in 28 areas, bringing the total number to 160. Twenty-six areas instituted artificial light treatment and 56 new specialist officers were appointed, including 33 new dentists and 12 orthopædic surgeons. The school clinics are increasing rapidly; in 1910 there were 30 of them and now there are 1520. Of these, 936 deal with minor ailments, 1039 with dental defects, 569 with visual defects, 80 with enlarged tonsils and adenoids, and 150 with orthopædic defects, while 45 treat ringworm with X rays and 26 supply artificial light treatment. The attendances at these clinics fully justifies their extension; in 1914 it was 123,039; last year it had risen to 663,305.

About 10 per cent. of all children need visual correction, and during 1927 eight additional ophthalmic specialists and 15 new ophthalmic clinics were provided. Good results in the treatment of squint are reported from several districts. The incidence of enlarged tonsils and adenoids is about 5–6 per cent. among unselected school-children, and the causes are still obscure, though it seems probable that they are nutritional rather than environmental. Treatment is now provided at 461 hospitals and 80 school clinics, the total number of children operated on being 80,548—about half of those referred for treatment. For chronic nasal catarrh diastolisation is being tried in Liverpool and London and is giving encouraging results. The essence of this treatment is massage of the nasal passages by soft inflatable rubber bougies. It is said to be particularly well adapted to the relief of those conditions resulting from inability to breathe correctly. Ionisation is now in use by 40 local authorities for otorrhœa; the operative treatment of mastoid disease is undertaken by 32, and other special forms of aural treatment by 31. The incidence of dental disease varies little; in 1927 it was found in 64·6 per cent. of "routine" cases. This does not mean that the treatment provided is without value, for the number of unsaveable permanent teeth diminishes year by year.

The Board are seeking detailed records of the effect of artificial light treatment, but so far little material is available. General inferences show that there is almost universal agreement as to the tonic value of light on tired and languid children, but the evidence for specific effect on particular ailments is conflicting or indefinite, and on the whole negative. The prevention of crippling demands the efficient working of a comprehensive scheme, such as is described from Lancashire. Birmingham found that 84·5 per cent. of non-tuberculous crippling occurred before school age. Delay means longer treatment at greater cost with worse prognosis. Increasing attention is being given to the treatment of postural defects in special clinics.

Nursery Schools and Special Schools.

The increasingly significant problem of the pre-school child is being dealt with in 27 centres at present by "nursery schools"—which resemble homes rather than schools. The aim of nursery schools is to prepare children from 2 to 5 years of age for their school life by providing them with abundance of light, air, and nourishing food, and training them in good habits. The distinction between work and play disappears; the children work when they think they are playing and play when they think they are working, all the while growing strong and cultivating an alert and receptive attitude of mind. The nursery school is an important factor in the correlation of infant welfare work and school medical service.

Evening play centres now number 273, with an average total attendance of 59,000. Several new open-air schools have been opened, and the special educational needs of the children who attend them has received careful attention. The curriculum, while it is less formal than that of the ordinary school and perhaps covers a smaller superficial area, yet has greater depth and is experimental, practical, and intuitive. Playground classes in ordinary schools are also being encouraged in many districts and much improvement in intelligence and alertness has been noted as a consequence. Two new special schools for mental defectives have been opened and two more are projected; the number of mental defectives ascertained during 1927 was 33,000. Through the activity of the Commonwealth Fund Dr. Ralph Crowley, the Board of Education's senior medical officer, visited the child guidance clinics in America last autumn; at present London, Bath, and Stoke-on-Trent are the only areas where any clinic provision is made for the nervous or maladapted child of this country. There are six special residential schools for epileptic children, of whom 2652 were notified as unfit to attend school during 1927. The special schools can only provide for 525, and there is therefore grave need for further accommodation for this group. Classes for stammering children have been conducted in some 30 areas. Blind and partially blind children ascertained during the year numbered 1925 and 4929 respectively; the numbers have decreased considerably. The numbers of the deaf and partially deaf requiring special education were 6091. Their needs are the subject of a special article in the Report.

There seems to be considerable room for improvement in the standard of cleanliness, heating, and lighting in school buildings, and there are still too many obsolete desks. Defects of this kind go far to counteract the work done by the medical inspection and treatment, and call for vigorous and persistent action by the education authorities.

The Secondary School-child and the Young Worker.

The report shows that the health of the secondary school-child compares favourably with that of the elementary scholar, but fuller and more careful records are needed to estimate the relative importance of such factors as strain, extra-school environment, and age on the production of minor abnormalities, which are rather frequent. The elementary school-child, moreover, is improving physically at a greater rate than is the secondary school-child. Although the latter has better school premises, playing-fields, and often substantial mid-day meals, yet he has a longer journey to school very often, longer hours, more home-work, and less satisfactory facilities for the treatment of minor ailments. The remedies suggested are closer supervision of personal hygiene and careful attention to the suitability of the child for scholarship work and for the calling selected for him. The crucial question for the school medical service is whether or not the schools are turning out a better worker year by year, and there is evidence that the physique and health of the leaving child is improving steadily. Thereafter, however, he tends to go backward in health, and the Board is commendably exercised with the adolescent health of its ex-scholars. Education needs to be linked up with employment, just as infant welfare needs to be linked up with school. In many areas the juvenile employment bureau and juvenile advisory committee is in intimate coöperation with the education committee. The certifying factory surgeon, according to Sir George Newman, should also have access to school medical records, and there should be greater uniformity in the meshes of the various sieves through which a young person passes before being accepted for employment. Many private schemes of factory welfare bridge the gap of two years which the State

has left during the critical phase of adolescence. The report reviews a number of these, and looks forward to much more intimate coöperation between them and its own medical service, and to some scheme of the same kind which shall cover all adolescents who at present are no one's special care.

Health Education.

The chief medical officer expresses the opinion that the lack of effective teaching of hygiene is the weakest link in the whole chain of child welfare. The injuries due to ignorance should be prevented, and the study and practice of health should form, from the first, part of the everyday life of the school. Hygiene must not only be taught but must also be practised day by day; otherwise there is no momentum to carry the teaching through adolescence and adult life. Every teacher should bear in mind his direct responsibility in this matter to every individual child. The Board has recently published a special new "Handbook of Suggestions," to constitute a guide in the teaching and practice of hygiene, and regards a knowledge of its contents as part of the necessary equipment of every teacher. The Board is also anxious that girls should learn the first principles of mothercraft, for if they do not learn them at school they are unlikely to have any opportunity for organised teaching afterwards. In elementary schools the girls can visit local welfare centres or day nurseries; the secondary school-girl can approach the subject through elementary science.

Physical Training, School Meals, and Research.

Organised physical training has been a part of the school curriculum for 20 years, and admirable effects have been produced, but the work is still expanding. The Board has decided to advise local authorities to embark on a general reorganisation which will involve changes in the physical training, and this report therefore reviews rather fully what has been done and the proposed amendments. The provision of meals for school-children is increasing; nearly 16,000,000 meals were supplied in England and Wales during the year, half of them being dinners. The danger of turning this provision into an unauthorised kind of poor relief can only be met through medical certification and direction.

The list of research investigations made by school medical officers and special workers is a long one. The subjects studied include postural defects, goitre, infectious diseases, rheumatism, stammerers, backward children, tonsils and adenoids, ringworm, ventilation, and ultra-violet light. The Anthropometric Committee has continued its valuable work.

Conclusion.

The general conclusion formed by the chief medical officer is that, while there is as yet no sign of diminished incidence of the ordinary physical defects of school life, there is, nevertheless, evidence that the general physical condition, as shown by physique, health, nutrition, and cleanliness, tends steadily to improve. The school doctor has an important part to play in the medico-educational problems of the nation; he must keep his horizon wide, take a broad view of medicine, understand his affinities with the educationist and the psychologist, and thus play his proper rôle in the creation of the right school environment during the passage from childhood to adolescence. The report will encourage all who are collaborating in this great national scheme to persevere in their duties though these may seem arduous, dull, and sometimes unproductive. Sir George Newman points out that the routine work of the school medical officer has a vastly wider purpose than the collection of medical statistics and even the individual relief of the patient. It makes practicable a fuller education of the people as a whole, and is the prelude of national efficiency. In the audit and account of this work may be found a service of science and humanity which is silently but certainly changing the prospects and hopes of the English people.

MEDICINE AND THE LAW.

A Vinegar Prosecution.

THE last annual report of the Ministry of Health recorded the fact that 1553 samples of vinegar were taken under the Sale of Food and Drugs Acts during 1927; of these, 142 were found to be adulterated or not up to standard, chiefly by reason of the deficiency of acetic acid. The percentage seems unduly high; it works out at 9·1 as against a figure of 6·2 for 1926. In some cases vinegar sold as "malt vinegar" was found to be not brewed but artificial vinegar. A case has recently come before the Divisional Court which seems to indicate a disinclination on the part of magistrates to take a serious view of adulteration. A prosecution took place before the Atherstone bench on a charge of selling table vinegar which was 100 per cent. artificial. The magistrates, according to a summary of the case in the *Solicitors' Journal*, dismissed the summons on the several grounds that there was (*a*) no statutory standard of vinegar, (*b*) no evidence of guilty knowledge, and (*c*) no reason for imposing a penalty upon a defendant who had acted in good faith. The inspector appealed on the ground that the county analyst had proved that three grades of vinegar exist; but the appeal was countered by the plea that the magistrates had dismissed the case under the Probation of Offenders Act and that their decision could not now be disturbed. The Probation of Offenders Act was not apparently mentioned in the "case stated" which came before the Divisional Court; the fact was merely recorded that the magistrates dismissed the summons because no offence had been committed. The Lord Chief Justice observed that the allegation that the vinegar was 100 per cent. artificial was uncontradicted, and that, as the defendant called no evidence, the magistrates ought to have found the charge proved on the uncontradicted facts. The Divisional Court remitted the case to the magistrates with a direction to that effect. The result is somewhat obscure. If the magistrates were acting under Subsection 1 (1) of the Probation of Offenders Act, 1901 (as the defendant apparently contended on appeal), then they must already have considered the charge to be proved; otherwise they could not have acted under that particular enactment. The statute provides that, if the court of summary jurisdiction thinks that the charge is proved, but is of opinion that the character, antecedents, age, health or mental condition of the accused, or the trivial nature of the offence, or the existence of extenuating circumstances, make it inexpedient to inflict any punishment or any other than a nominal punishment, or to release the offender on probation, then the court may, *without proceeding to conviction*, either dismiss the charge or bind the accused over. The Divisional Court may give the Atherstone bench a strong hint of its opinion, but, if that bench is determined to operate the Probation of Offenders Act in this particular case, the magistrates can still dismiss the charge without proceeding to conviction. One result of sending the case back to them may be a little additional local publicity for the facts alleged in the summons. The Food and Drugs (Adulteration) Act, 1928, now in force, states the law perfectly clearly: "No person shall sell to the prejudice of the purchaser any article of food or any drug which is not of the nature, or not of the substance, or not of the quality, of the article demanded by the purchaser." If it is to be a defence that the law specifies no standard of what is vinegar (or any other article), the law had better be amended.

A Coroner's Dilemma.

Parliamentary draftsmen are probably not sanguine enough to believe that they can think of every contingency. A small gap in the Coroners Acts is disclosed in the legal journals. The amending Act of 1926 had a provision (Section 20) to avoid the simultaneous progress of investigations into cases of

murder, manslaughter or infanticide, both before a coroner, on the one hand, and before examining justices and assize courts on the other. The coroner "in the absence of reason to the contrary," is to adjourn his inquest "until after the conclusion of the criminal proceedings." The clerk of the appropriate court is to inform the coroner of the result of those proceedings and, if the coroner then decides not to resume the inquest, the coroner furnishes the registrar of deaths with a certificate stating the result of the proceedings and including any necessary particulars. An inquest was begun last year upon the death of a child. The magistrates committed the child's mother to the November Assizes on a charge of wilful murder. The coroner apparently adjourned his inquest as directed by the 1926 Act. The next step, however, contemplated by the statute cannot be taken. The Home Secretary has ordered the woman's removal to an asylum: she will now not be tried, and consequently the "proceedings" cannot be "concluded" with any "result" of which the coroner can be officially informed. Thus, it would seem, the inquest must take its course. The coroner has found himself obliged to issue a warrant against the mother, bind over the police superintendent to prosecute, and bind over the witnesses to appear and give evidence. It would have been feasible to take the poor woman to the assizes for the formal purpose of obtaining a verdict of "Guilty, but insane." Quite apart from the expense of this course, however, public opinion would deprecate it.

An Unregistered Dental Association.

A case was recently heard before the Oldham borough justices in which a manager of the Co-operative Wholesale Society (Health Insurance Section) was summoned for "practising or holding himself out to practise dentistry," his name not appearing in the Dentists Register. It was argued on behalf of the British Dental Association that it was not essential for the commission of an offence of this kind, that the person should be the actual one who performed the operations of dentistry. A body corporate or limited company could carry on dentistry if the majority of its directors and all its operating staff were dentists, though not otherwise. It was stated that the C.W.S., being an approved society under the Health Insurance Acts, had not agreed to an increase in the scale of dentists' fees in 1926, and despite the fact that it was not a registered organisation under the Dentists Act, had endeavoured to set up dental clinics in certain northern towns. An unregistered dental surgeon had been given charge of such a clinic at Oldham where there was a clerk and four dental mechanics, and patients had been treated there on behalf of the Co-operative Dental Benevolent Association, which was unregistered under the Act. In defence counsel argued that responsibility for what had been done lay with the Association and not with its salaried manager. The chairman and the bench were of opinion, however, that the latter had unlawfully held himself out as practising dentistry and fined him £50, also awarding £25 costs to the prosecution. They agreed to state a case for appeal to the High Court.

Two Deaths Under Anæsthesia.

Arrangements at the Weir Hospital, Balham, were criticised at an inquest on Jan. 2nd on a boy of 4 who died in the institution whilst a fracture of the leg was being reduced under an anæsthetic. There are two resident doctors at the hospital but one of them was away when the child was brought for treatment. The resident medical officer first administered open ether and then instructed a nurse to hold the mask while he reduced the deformity. Death followed from heart failure, despite employment of artificial respiration and stimulants, and at autopsy it was found that the boy had a full stomach which adhered abnormally to the liver. The coroner, in recording a verdict of death by misadventure, said that the resident medical officer had exercised careful judgment in the circumstances, was justified in administering the anæsthetic, and did so properly. At the same time he considered it distinctly inadvisable that the hospital should be left with only one doctor, since only in grave emergency should a medical man play the dual part of anæsthetist and surgeon. It was stated in evidence that the hospital had two visiting surgeons, but it was not customary to call them in except for big operations.

On Jan. 8th the Westminster coroner recorded a similar verdict in the case of a boy of 2 who died during an operation at Charing Cross Hospital. Post mortem large pieces of undigested food were found in the stomach and the pathologist, in ascribing death to syncope, said that the presence of food was probably in part responsible for the accident. The mother said she had not received any instructions about meals, and the doctor who gave the anæsthetic said that she (the doctor) had not seen the child on any previous occasion. The anæsthetic was ethyl chloride, followed later by a mixture of chloroform and ether. The coroner remarked that he thought it was the common practice in hospitals to warn parents not to give their children meals a few hours before anæsthetics would be administered.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Study Leave.

THE refusal of the Minister of Local Government and Public Health to sanction the proposal of the Grangegorman Mental Hospital Committee to give one of their medical officers six months' study leave with pay has given rise to criticism. As was pointed out by a member of the committee, the institution would benefit by the course of study which Dr. J. Dunne proposed to pursue. Another member mentioned that the Minister of Defence had thought it wise to send young officers to study the methods of foreign armies.

The lack of any provision for study leave is a grave fault in the public medical services of the Irish Free State. The Committee of Inquiry on National Health Insurance and the Medical Services in its Interim Report in 1925 made a strong recommendation in favour of the grant of study leave at regular intervals to dispensary medical officers. It was recommended that a period of not less than three months should be given at least as often as once in every five years, and that evidence of having taken advantage of such opportunities should receive consideration where promotion was in question. During such leave the medical officer should receive full salary without deduction for payment of a substitute, and a grant should be made to cover fees for study. It is possible that such a procedure might require legislative authority, but there appears to be no good reason why the Government should not before now have taken action on the Report of the Committee of Inquiry.

The 83 (Dublin) General Hospital.

The annual dinner of the Dublin Unit which staffed the 83 General Hospital, B.E.F., in 1917–18, was held last Saturday night in the Council Room of the Royal College of Surgeons, Colonel Sir William Taylor presiding. Some 15 members of the unit were present.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

The New Health Department.

THE Scottish Department of Health came into existence on Jan. 1st. The Scottish Board of Health passed out of existence on Dec. 31st. In point of form the Board was a survival from an older and more amateurish conception of Government service. It was essentially an advisory board with no powers

apart from the President, and, in many respects, quite unsuited to the work of executive administration. The new department is organised on the same general lines as the Ministry of Health. Personal responsibility, under the political direction of the Secretary of State, becomes once more a possibility and a reality. But, in 1919, when the Board of Health was formed, it would have been, for historical reasons, difficult to establish the present type of department. Fortunately, its establishment coincides with the projected revolution in local government. The new department ought, therefore, to be decidedly fruitful for Scottish government, both central and local.

Housing.

At a Conference of the Scottish Labour Housing Association in Glasgow, the Rev. James Barr, M.P., who was for two years a member of the Royal Commission on Housing, gave some striking figures from that report and from subsequent returns. The Commission, in 1917, estimated that Scotland had a shortage of 121,000 houses, without allowing for natural expansion of population and without exacting a higher standard than three persons per room (as against England's two). In 1919 the local authorities themselves admitted a need for 113,000 houses. The Board of Health's estimate in subsequent years was that for every ten years from 1919 there should be added 10,000 houses yearly, thus increasing the shortage to 213,000 houses. Scotland is thus, on official figures, still about 100,000 short. Meanwhile, the local authorities and the central department have been very active, and it is estimated that, including both subsidised and unsubsidised houses, about 100,000 new houses have now been provided. Of these, about 90,000 are subsidised houses built by local authorities or by private persons. In 1928, I am informed, the total built was about 18,000. In 1927 it exceeded 20,000. There is, however, no real falling off, the lesser number in 1928 being due to the fact that there are no new steel houses. There are signs of renewed pressure for an increase of two-room houses. This indicates a failure to grasp the true position. Scotland has already many times more two-roomed houses in proportion to the number of larger houses. And two rooms, it is to be remembered, mean literally just two rooms, not, as it might in England mean, a kitchen and two bedrooms. The industrial world is slow to grasp the simple arithmetical fact that you cannot house a family of seven in two rooms without producing an overcrowding that exceeds three persons per room. As to the one-room house, public opinion is agreed that it should go; but the fact remains that several hundreds of thousands of people in Scotland occupy houses of one room, sometimes very grossly overcrowded. There is still, therefore, a long programme to work off and the next 20 years will not see the end of it.

A Radium Institute for Scotland.

It is satisfactory to learn that the managers of Edinburgh Royal Infirmary have approved of a scheme to establish a radium institute which will be the first in Scotland. For this purpose they have decided to reconstruct a property at Murrayfield, and to contribute, if necessary, a sum of £40,000 from the unrestricted finances of the infirmary. A gift of £10,000 has already been made for the purchase of radium for a Glasgow hospital, and Edinburgh, with its great traditions as a centre of medical science and skill, should not be behindhand in this development. It is intended that the radium institute should be capable of accommodating 30 in-patients, and of serving the needs especially of Edinburgh and the south-east of Scotland. It is eminently desirable that the supply of radium should be concentrated in one or two centres, instead of being distributed among various local hospitals. Local needs can much better be satisfied by providing for the attendance of patients at the central institute, where they will obtain the advantages of the most complete technical equipment and the most expert skill in utilising it. A radium institute has been established in London, and similar facilities are available in some provincial centres in England. But Scotland has hitherto lacked such a centre, the establishment of which will undoubtedly meet a felt need. Government assistance may be expected in obtaining an adequate supply of radium, and public support should not be lacking towards the proper equipment and development of the institute.

Training of Nurses.

In moving the adoption of the annual report of the Scottish Branch of the Queen's Institute of District Nursing, Dr. J. Parlane Kinloch, chief medical officer of the Scottish Department of Health, said the time was opportune to survey the whole position of the nursing service in its relation to public health work. Training schools for nurses had been recognised by the General Nursing Council under the Nurses Registration Act of 1919. It was a serious reflection on hospital authorities generally that the endeavour to link up the general hospitals with the fever hospitals, the sick children hospitals, the maternity hospitals, the mental hospitals, and the special hospitals, with a view to providing a common training school for nurses, wherein the probationer nurse could receive within a period of four years a comprehensive training in nursing methods, had been unsuccessful. It was only necessary to look to the medical training schools to recognise what this failure to organise the nurses' training schools really meant. The great training centres in Scotland were doing increasingly admirable work, but he thought there had been a tendency to overdo the drilling in our great hospitals. If machine-like drilling was carried into the ward it swamped personality. The biggest thing that could happen to the nursing profession was for the authorities of our voluntary and statutory hospitals and for the Council of the Queen's Nurses to use their prestige and influence to bring those bodies about and get regional training schools for nurses built around the walls of the four universities of Scotland.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

"Christian Healing."

SOME interest has been aroused in medical circles by the report given recently by a Commission of Bishops and Deputies to the General Convention of the Protestant Episcopal Church. This Commission has been considering evidence of "Christian healing" since its appointment three years ago and has heard physicians and neurologists as well as parish priests and the hearsay testimony of persons of unquestioned veracity. On the one hand the Commission recommended that all faith-healing should be carried on in close coöperation with medical science, but on the other they state that throughout the world spiritual healing is no longer the hope of a few but the belief and practice of a large and rapidly increasing number of persons. On these conclusions the *Ohio State Medical Journal* has the following editorial comment:

A proper spiritual attitude cannot help but be beneficial to a physician who serves his patients with a reverence for the forces of God. In like manner, a spiritual and reverential attitude on the part of the patient is desired, but to assume that faith or religion even in a small measure can be a substitute for definite medical sciences is fallacious. Too many instances have been recorded where religious zealots neglected and ignored physical conditions such as cancer, tuberculosis, diabetes, and Bright's disease until even their own "faith" could not prevent them from suffering a painful and early death.

Income-tax Deductions.

Six years ago the Commissioner of Revenue denied to physicians the right to deduct from their taxable incomes the expenses incurred in attending professional meetings. Since then the American Medical

Association has carried on a consistent campaign for the reversal of this decision. Legislation favourable to the Association's claims was passed through the Senate during the last session of Congress but lost in a compromise with the lower house. Now a legal victory has been won through an appeal to the Board of Tax Appeals. The physician who fought the test case had expended during the years 1920, 1921, 1922, and 1923 the respective sums $16, $230, $375, and $384.46 for "railroad fare, accommodations, and meals" in connexion with meetings of medical associations. He had not been allowed to deduct these sums in whole or in part from his taxable income. The Board of Appeals has overruled the Commissioner's decision, and unless an appeal is made by the latter to higher courts before April, 1929, the ruling will become final and within certain time-limits will be retrospective. It is estimated that the medical profession has paid as much as half a million dollars under the former ruling and that a large part of this sum will be recoverable.

Negative Results with Tubercle Vaccines.

The results of experiments with two different vaccines were reported on Dec. 6th to the National Livestock Sanitary Association by Stillman J. Stanard, director of agriculture of Illinois. From the scanty press accounts as yet available it appears that one vaccine was the celebrated B.C.G. and the other a ricinoleated vaccine prepared by Dr. Larson, of the University of Minnesota. Ten infected cattle were added two years ago to a herd of 60 tuberculin-tested cattle. The latter consisted of 20 controls and 20 animals immunised by each of the two vaccines. It appears that after two years autopsies of this herd show that only a few of the animals "immunised" with the Larson vaccine had escaped infection; all the controls and all animals "immunised" with B.C.G. were infected.

Rejuvenating Epithelium.

For some years past Dr. Joseph Franz Kapp, of New York, has been working on a method for rejuvenating the epidermis at the time of life when it begins to share in the changes of senescence. By immunising rabbits with a maceration of the skin of young pigs he obtained a serum which, when administered subcutaneously, led to an increase in mitosis and a restoration of capillaries in the derma. A preliminary report, recently presented by Dr. Kurt Holzapfel, of Berlin, and himself, deals with the effect of this novepithel, as it is called, on 71 cases of various skin affections. It proved wholly or partially successful in cases of bedsore, eczema, ulcus cruris, alopecia, zoster, and scleroderma, while the effect was small or absent in psoriasis and rosacea. The results, they suggest, are sufficiently favourable to warrant further investigation on a large scale. At present the serum is being tested at the Berlin Charité by Prof. Friedr. Kraus, in Vienna by Prof. Alf. Perutz, while Prof. Erich Hoffmann is trying experiments on a large scale at the Dermatological Clinic of Bonn. The preparation is not yet on the market in America, but it has been placed at the disposal of dermatologists, such as Dr. J. Eller at the New York Post-Graduate Hospital, Dr. Conrad Miller, of Chicago, and Prof. Otto Lerch, of Tulane. Kapp himself was stimulated to further trial of the preparation by finding it promise well for the tormenting pruritus of elderly persons.

Valentine Mott.

At a recent meeting of the New York Academy of Medicine Dr. Louis F. Bishop, of New York, read a paper on Valentine Mott, a surgeon who in his day enjoyed an international fame for deftness of hand and boldness of execution little less than that of his London teacher, Sir Astley Cooper. It is remarkable that at the time of his graduation in 1806 Mott gave no indication of his interest in surgery, and concerned himself chiefly with chemistry; but the teaching and example of Cooper developed in the New York physician a zest for surgery which grew more and more keen the longer he remained in London. After leaving Cooper's influence, Mott, as was then the custom with young American medical graduates, proceeded to Edinburgh, where he sat at the feet of Gregory, Home, Duncan, Hope, and Playfair. Two years after his return to New York he was elected to the chair of surgery at Columbia College. In his sketch of Mott's professional life Dr. Bishop claimed that he was the first to deliver private lectures in America on any medical subject, and the first to demonstrate to a class the steps of surgical operative surgery as then practised.

THE CONGRESS OF MEDICINE IN EGYPT.

OVER 2000 medical delegates and members of the medical profession, drawn from Europe, North and South America, the Near and Far East, gathered in Cairo on Dec. 15th last for the twofold purpose of celebrating the Centenary of the Cairo Faculty of Medicine and joining in a Conference on Tropical Medicine and Hygiene.

Since Clot Bey was first summoned from France by Mohammed Ali in 1825 to inaugurate a medical service in Egypt, enormous strides have been made, and if during the first half of this period progress was slow, and even at times interrupted, during the last 50 years a hospital service, a centre of medical education, and a public health administration have emerged which reflect immense credit upon the Governments by which they have been fostered, and afford an enduring memorial of the many notable men—such as Bilharz, Sandwith, Milton, Keatinge, and Loos (to mention only a few) who have chiefly shaped the course of events. It was right that advantage should be taken of the Centenary celebration to invite the attendance of representatives from all over the world to see for themselves how surely the foundations of Egyptian medicine have been laid, how bright are the prospects for its future, and with what zeal the problems of preventive and curative medicine peculiar to the land of Egypt are being tackled. The British delegation was numerically small but representative, including, amongst others, Sir George Newman, Sir Robert Philip, Sir Berkeley Moynihan, Sir Holburt Waring, Sir StClair Thomson, Sir William de Courcy Wheeler, Sir Frank Collyer, Dr. Monro Kerr, Prof. Nuttall, and Dr. J. B. Christopherson.

The Proceedings of the Congress.

The proceedings opened on the morning of Dec. 15th with a function in the Opera House attended by H.M. King Fuad. After an introductory address by the President of the Congress, His Excellency the Minister of Education, addresses were presented by representatives of the Governments of France, England, United States of America, Germany, Italy, Greece, and Japan, Sir George Newman being the English spokesman. The same afternoon King Fuad opened in state a Medical and Sanitary Exhibition in the grounds of the Royal Agricultural Society, in which the Egyptian Department of Public Health had staged an attractive display of models illustrating every phase of the work now proceeding.

The following morning, Sunday, the 16th, in a marquee of colossal proportions and oriental design, H.M. the King laid the foundation-stone of the new Hospital and Medical School which is on the point of being built to take the place of the historical Kasr-el-Aini Hospital. This new hospital is designed to provide 700 beds, and the site available—an ideal one upon Roda Island—allows ample room for medical school, students' hostel, and sports grounds immediately adjacent to the hospital. The plans available for inspection suggest that with the abundant funds at their command the architects have designed a group of buildings that will be the envy of many a larger city than Cairo. Later the same day a large

audience was presided over by Sir Berkeley Moynihan, who, as President of the Royal College of Surgeons of England, conferred the diploma of Fellow upon Ali Bey Ibrahim, Professor of Clinical Surgery and Sub-Dean of the Faculty of Medicine. The enthusiasm aroused in the audience by this compliment paid to an outstanding surgeon and a popular personality lasted on for the next two hours, during which a never-ending procession of delegates made their bow to the President of the Congress and handed him their addresses.

The Work of the Congress.

The work of the Congress proper, which started on Monday, Dec. 17th, was divided up into 16 sections devoted to such subjects, among others, as medicine, surgery, bilharziasis, dysentery, tuberculosis, leishmaniasis, and malaria, and sessions were held of some or all of these on the mornings of five days. Résumés of the chief contributions, which were delivered in either English, French, or German, were printed and circulated for the benefit of delegates, who were thus enabled to select the place of their attendance to their individual taste. The chief interest perhaps centred round the subjects of special local importance, such as tuberculosis, trachoma, bilharziasis, and pellagra, and it is only necessary to mention that Drs. Van der Hoeve, Giemsa, Schuffner, Castellani, Christopherson, Ashford, and Wilson took part, to ensure that the Proceedings of the Conference, when they appear, will be studied with especial interest. Whilst the attendance at the sectional meetings was good, it must be confessed that a punctilious devotion of five mornings to the Congress seemed too much like work to many of those who had come long distances to visit Egypt for the first time, and many a Congress badge—a charming gilt emblem of Im-Hotep—was to be seen in the Cairo museums, the mosques, and elsewhere during Congress hours.

At the official closing of the Conference in the afternoon of Dec. 22nd, 13 honorary degrees of the University of Cairo were conferred upon delegates.

Social Events.

A full programme of social events filled up the afternoons and evenings. The King received the whole company in the Abdin Palace on the opening night. The following evening the capacity of Shepheard's Hotel was fully taxed on the occasion of the official dinner presided over, in the absence of the Prime Minister through ill-health, by His Excellency Shahin Pasha, and on yet another evening Their Excellencies Lord and Lady Lloyd had invited British delegates and others to an evening reception at the Residency. Tea parties at the Medical School, at the Pyramids, and at the Delta Barrage were most popular afternoon functions.

The warmest praise is due to the Organisation Committee, owing to whose efforts everything passed off without difficulty or hitch, in spite of the large numbers, while a special word of thanks is due to the Ladies' Committee, whose organisation enabled those accompanying the delegates to visit the sights of Cairo and the neighbourhood under expert guidance. Special concessions granted by the railway companies and the hotels assisted materially those who wisely wished to combine with their attendance at the Conference visits to the treasures of Upper and Lower Egypt. The opportunity so afforded of seeing the antiquities and gaining an insight into the Medical School of Cairo and the problems of public health which face the Egyptian Government made the visit of those fortunate enough to be able to attend a very memorable one.

METROPOLITAN ASYLUMS BOARD.—The Board has approved a scheme, costing about £30,000, for the provision of a new nurses' home at the Downs Hospital for Children.

RESEARCH ON TUBERCULOSIS.—Mr. Halley Stewart has given £700 a year for five years towards special research at the Brompton Hospital for Consumption and Diseases of the Chest.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH FOR 1928.

THE customary circular, lately issued by the Ministry of Health, shows that the 1928 reports are to be ordinary, and not "survey," reports. Attention to new features is drawn by marginal lines.

The circular announces that the Registrar-General will distribute his short list of the causes of death in the various districts in February or March, 1929, with the exception of the county aggregates, which will be distributed in April. The hope is expressed that this early distribution of the figures will enable each report to be completed not later than the middle of May. Reference is made to the fact that in certain districts local estimates of population and classification of deaths are preferred, but it is particularly requested that when this is the case the Registrar's figures shall also be included in the report in order to facilitate comparison with the figures for other areas. The Registrar-General receives frequent applications from medical officers of health for information as to the death-rates in the whole country from cancer, from pulmonary and other forms of tuberculosis, and from childbirth, and to obviate the necessity for such applications, the death-rates mentioned will be published in the Registrar-General's Weekly Return as soon as the necessary data are available.

The following are some of the matters emphasised in the circular. Particulars are to be given of the amount, situation, and nature of accommodation, and by whom provided, of clinics and treatment centres of all kinds, including orthopædic and light clinics. Full information is demanded as to applications for the registration of maternity and nursing homes and the result of such applications. Up to July 1st this will only apply to maternity homes, but after that date to both maternity and nursing homes. County councils are also required to give particulars of applications for the delegation of their powers under the Nursing and Maternity Homes Registration Acts. Any special arrangements made for the investigation of maternal deaths and cases of puerperal fever are to be described.

The results of the analyses of public water-supplies, whether piped or not, are specially asked for. Other matters stressed include the adequacy of the arrangements for the disposal of the dead; arrangements made for the publication or dissemination of knowledge relating to health or disease; particulars of inspections made or actions taken under the Rag-Flock Acts, 1911 and 1928; action taken under the Food and Drugs Acts, including the Public Health (Preservatives, &c., in Food) Regulations, 1925–1927); particulars about work done at laboratories for the chemical and bacteriological examination of food; the prevalence of animal or insect pests, such as rats or mosquitoes, and the measures taken for their suppression; and particulars of action taken under Section 66 of the Public Health Amendment Act, 1925, for the prevention of blindness or the treatment of persons suffering from any disease or injury to the eyes.

The study of these annual reports followed by the perusal of the circular leaves one in the hope that the day is not far distant when the decision of the Registrar-General as to estimates of population and classification of deaths will be accepted as that of an umpire, and that before long, perhaps with the good offices of Geneva, we shall have one system of classifying deaths associated with childbirth in every country in the world.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 29TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 131 (last week 201); scarlet fever, 2275 (last week

2451); diphtheria, 1225; enteric fever, 40; pneumonia, 1616; puerperal fever, 43; puerperal pyrexia, 86; cerebro-spinal fever, 6; acute poliomyelitis, 2; acute polio-encephalitis, 1; encephalitis lethargica, 14; dysentery, 4; and ophthalmia neonatorum, 94. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified in the following 17 counties: London, 10 (Poplar); Chester, 2; Derby, 12; Durham, 26 (Jarrow 13); Essex, 2 (West Ham); Huntingdon, 1; Lancaster, 10; Leicester, 6 (county borough); Northampton, 6 (county borough); Northumberland, 10 (Tynemouth C.B.); Nottingham, 9; Soke of Peterborough, 2; Stafford, 3; Yorks, West Riding, 12 (Halifax 7); Brecknock, 1; Glamorgan, 13; Monmouth, 6.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Jan. 1st–2nd was as follows: Small-pox, 28 (4 under treatment); scarlet fever, 2248; diphtheria, 2201; enteric fever, 19; measles, 37; whooping-cough, 530; puerperal fever, 23 (plus 5 babies); encephalitis lethargica, 74; poliomyelitis, 5; other diseases, 28. At St. Margaret's Hospital there were 13 babies (plus 4 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 24 (0) from measles, 13 (1) from scarlet fever, 56 (18) from whooping-cough, 52 (8) from diphtheria, 49 (5) from diarrhœa and enteritis under two years, and 83 (15) from influenza. (The figures in parentheses are those for London itself.) The number of deaths from influenza during the previous seven weeks were 68, 72, 49, 56, 60, 61, and 69 respectively.

The fatal cases of enteric fever were reported from Grimsby and Sheffield. Liverpool reported 7 deaths from measles, Cardiff 3, whilst Lincoln, Middlesbrough, and Newcastle-on-Tyne had 2 each (Belfast 7). There were 8 deaths from whooping-cough in Manchester, 6 in Leeds, and 4 in Salford. Five deaths from diphtheria occurred in Liverpool, whilst Liverpool also reported 4 deaths from diarrhœa. Outside London the largest number of deaths from influenza was Birmingham, 6; Manchester reported 5, Liverpool 4, and Stockport, Leeds, Hull, and South Shields 3 each. (The figure for Glasgow was 7.)

The number of stillbirths registered during the week in the great towns was 264 (corresponding to a rate of 55 per 1000 total births), including 41 in London.

The Services.

ROYAL ARMY MEDICAL CORPS COMMISSIONS.

A LIMITED number of commissions in the Royal Army Medical Corps without entrance examination are being offered to qualified practitioners under 28 years of age. Applications should reach the War Office not later than Jan. 25th, and information as to conditions of service and emoluments may be obtained from the Under Secretary of State, War Office (A.M.D.1), Whitehall, London, S.W. 1.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. N. S. Meiklejohn to be Surg. Capt.

Surg. Lt.-Comdrs. (D.).—A. T. Dally to *Pembroke*, for R.M. Infirmary, Deal; J. T. Wood *to Vivid*, for R.N. Hospl., Plymouth; M. F. Hopson to *Pembroke*, for R.N. Barracks; and W. E. A. Sampson to *Vivid*, for R.N. Barracks, Devonport.

Surg. Lts. E. W. Graham to *Victory*, for R.N. Barracks, Portsmouth; R. G. E. Richmond to *Pembroke*, for R.N. Barracks, Chatham; and H. S. Marks to *Vivid*, for R.N. Barracks, Devonport.

ROYAL ARMY MEDICAL CORPS.

Capt. G. H. Barry to be Maj. (Prov.), and remains secd.

D. Blewitt to be Lt. on prob.

ARMY DENTAL CORPS.

Capt. G. A. Ballantyne resigns his commn.

ROYAL AIR FORCE.

Squadron Leader A. Grant to be Wing Comdr.

INDIAN MEDICAL SERVICE.

Lt. W. Scott to be Capt. (prov.).

Correspondence.

"Audi alteram partem."

THE TREATMENT OF HÆMORRHOIDS BY INJECTION.

To the Editor of THE LANCET.

SIR,—I was greatly interested in Mr. Christopher Howard's article in THE LANCET of Jan. 5th on Submucous Injection of Hæmorrhoids with Quinine Urea Hydrochloride. As he writes, the method he describes differs from my own mainly in the choice of the solution used and in minor details of technique. I myself tried using quinine urea hydrochloride some years ago. I did so with some trepidation, because a good many cases of serious sloughing of the skin had been reported after the use of this drug hypodermically as a local anæsthetic, although it had been used for that purpose in a strength as low as 1 per cent. I found that a 1 per cent. solution of quinine urea hydrochloride was quite ineffective for the treatment of internal hæmorrhoids and eventually I tried a 2 per cent. solution. Even this strength was found to be very variable in its action, and the symptoms, such as hæmorrhage and prolapse, did not yield immediately after the first injection in the way they almost invariably did to the strong carbolic glycerine solution which I was in the habit of using at that time. Nevertheless I encountered several cases of unpleasant sloughing even amongst the few cases which I treated with quinine urea hydrochloride, and where sloughs occurred there was a considerable amount of pain after the anæsthetic action of the solution had passed off. At that time I did not practise submucous injection, but deliberately injected the solution into the centre of the pile-mass. A priori, one would expect sloughing to take place more readily when the solution is injected submucously and when a considerable degree of distension of the submucous tissue is aimed at, and still more so when a solution as strong as 5 per cent. is employed. It was therefore with some surprise that I read in Mr. Howard's article of the success of this method in his hands and in those of Dr. Bensaude, of Paris. It is to be hoped that later on Mr. Howard will publish his further experiences with the treatment, dealing more particularly with the question of the permanence of the "cure." For my own part I have obtained such uniformly satisfactory results with the 5 per cent. carbolic in almond oil which I have been using for over two years (see THE LANCET, 1928, i., 543), that I do not feel tempted to make any experiments with other methods. Quinine urea hydrochloride has been used largely for the injection of hæmorrhoids in the United States of America, notably by Dr. Terrell and Dr. T. Chittenden Hill—but I gather that it has been superseded by the majority of "ambulant proctologists" there in favour of the carbolic-oil submucous injection.

One objection that I see to the use of a solution of quinine urea hydrochloride is that it is at best only very feebly antiseptic, and, if by some mischance the solution became contaminated, very serious results might follow. The carbolic-oil solution has the great advantage of being a powerful antiseptic and of being almost "fool-proof" from that point of view. Nevertheless I agree heartily with Mr. Howard that every detail of the procedure should be carried out with full aseptic and antiseptic precautions, *more especially because* the site of the operation is necessarily a septic one. From this point of view the tendency of quinine urea hydrochloride to produce an urgent desire to defæcate some ten minutes after the injection seems to me a rather grave disadvantage.

"There are more ways of killing a dog than by hanging it," and I have no doubt that there are other solutions equally as good as the 5 per cent. carbolic-oil solution; but the results I have obtained with this solution have been so uniformly satisfactory that I doubt whether there is anything better. The frequent appearance of articles in the medical press on various

methods of treating hæmorrhoids by injection and by other "ambulatory" methods shows that at last the profession has realised that operations on hæmorrhoids are disliked by patients and that the latter, too, are becoming aware that operation is not the only or the most satisfactory way of dealing with this common and troublesome ailment.

I am, Sir, yours faithfully,

ARTHUR S. MORLEY.

Upper Wimpole-street, W., Jan. 5th, 1929.

LONDON COUNTY COUNCIL (GENERAL POWERS) ACT, 1920.

To the Editor of THE LANCET.

SIR,—This Act, passed some years ago, has recently been put into action. One clause of the Act required that any medical practitioner, carrying on work of the nature covered by the Act, might send in an "exemption certificate" annually and so avoid taking out the licence which is necessary for all other persons. The underlying idea of the Act in question was undoubtedly good, in that it was a real attempt to protect the public from unqualified persons, who were getting bolder in irregular practice, and had even gone the length of installing X ray apparatus for the depilation of facial hair, "when nature in vagary mistakes for Thomas, Mistress Mary,"—a most dangerous and gross form of treatment. Quite apart from the efficacy of such a procedure, many of the people treated may, sooner or later, in place of a few hairs have telangiectases, if nothing more serious. It was felt therefore, much as the idea of yet another body being allowed to regulate the practice of a duly registered medical practitioner was resented, that the Act had been passed and it was our duty to obey it. The London County Council have been most helpful and sympathetic so far as the medical members of the British Institute of Radiology are concerned, and they have agreed (in lieu of the personal certificate signed by two medical practitioners) to accept a single certificate signed by officials of the Institute, together with a schedule of names, as complying with the requirements of the Act. In acknowledging the schedule the official of the L.C.C. made the following observations:—

"With regard to the question of inspection, I would point out that, provided the required certificate has been furnished in respect of an establishment carried on by a registered medical practitioner, the Council's officers have no power to inspect such establishment."

As one of the most objectionable features of the Act was the domiciliary visit of inspection to the consulting-room of a registered medical practitioner, I think you will do a great service by making the above comment widely known. There is much in the Act that appears capable of more than one interpretation, and it seems likely that this may have to be solved by a friendly action in the law courts, but such a question is hardly of immediate concern.

I am, Sir, yours faithfully,

London, W., Jan. 3rd, 1929. STANLEY MELVILLE.

TONSILLECTOMY OR GALVANO-PUNCTURE?

To the Editor of THE LANCET.

SIR,—I have read with interest Dr. Berkeley Way's lucid account of his attack of general staphylococcal infection (THE LANCET, Dec. 29th, 1928, p. 1367). Cases of the kind are not uncommon, but an invasion of the tonsil by *Staphylococcus p.* is surely very rare. I have never seen such a condition, and I cannot believe that in Dr. Way's case the primary nidus of the infection was in the tonsil. There was diffuse furunculosis, and what Dr. Way rather vaguely calls carbuncles, which I presume were very large furuncles. There were abscesses in the axilla, obviously not of tonsillar origin, and there were quinsies, which I presume were peritonsillar abscesses, and therefore behind the capsule. To entirely liberate the collections of pus from these pocks behind the tonsil a resection of the tonsil was necessary. Adhesions of the capsule to the peritonsillar tissue behind were, in the circumstances, inevitable, but could not be attributed to the effect of the cautery unless the burner had perforated the capsule, which one is careful to avoid doing when using the galvano-cautery.

These cases of diffuse staphylococcal infection last for months and are very troublesome. I have seen one which ran on for two years, but eventually yielded to an autogenous vaccine. One would think, however, that in Dr. Way's case a considerable auto-immunisation had taken effect by the time the tonsils were removed. I am unable to follow his reasoning when he suggests an analogy between a septic tooth and a septic tonsil. A tooth is a purely mechanical structure, designed for biting and mastication; the tonsil is a lymph gland with a highly specialised function; at present we know only of its protective action, but it may eventually be proved to be one of the endocrine organs. In the many hundreds of cases which I have treated with the galvano-cautery I have never seen any closure of crypts, nor any recurrence of sepsis; and the red vascular appearance of the mucous membrane quickly subsides under the continued use of the chloramine spray.—I am, Sir, yours faithfully,

W. S. WHITCOMBE, M.D.

Harley-street, W., Dec. 30th, 1928.

A TUDOR ACT OF INDEMNITY FOR UNQUALIFIED PRACTICE.

To the Editor of THE LANCET.

SIR,—I notice among the correspondence recently appearing in your paper relative to the above Act that its authenticity is questioned. Further, that information is desired as to whether the document at New Romney is a copy of the Statute or a proclamation. The document in question is undoubtedly authentic, having been found among a bundle of proclamations, dating from Henry VII.'s reign to the eighteenth century. In itself it is one of the many regular printed proclamations of the time, presumably sent down to the town from London, in the ordinary custom of those times.

That these valuable proclamations have been preserved is due to the care which successive town clerks of New Romney have given to the documents in their charge.

I am, Sir, yours faithfully,

M. TEICHMAN-DERVILLE (Major).

Littlestone, New Romney, Kent, Jan. 3rd, 1929.

PROGNOSIS IN UNOPERATED CASES OF EXOPHTHALMIC GOITRE,

INCLUDING TOXIC ADENOMA.

To the Editor of THE LANCET.

SIR,—May I ask for information from those surgeons and physicians who have treated many cases of Graves's disease on the question of prognosis in cases where the patient declines operation? To avoid confusion these cases may be divided into the following two classes: (*a*) primary Graves' (diffusely enlarged vascular thyroid with hyperplasia); and (*b*) secondary Graves' (including toxic adenoma and cases following simple goitre). The patient (usually female) is not interested in percentages of deaths and recoveries. What she wants to know is the prognosis, without operation, in her individual case.

The points, on which I should be grateful for information, distinguishing between (*a*) primary and (*b*) secondary Graves's disease are: (1) Is it possible to give a correct prognosis as to what will happen in the individual case which is not operated upon? 2. If this is possible, what are the signs and symptoms on which the prognosis should be based?

I am, Sir, yours faithfully,

C. HAMILTON WHITEFORD.

Plymouth, Dec. 28th, 1928.

OSLER AS EPIDEMIOLOGIST.

To the Editor of THE LANCET.

SIR,—The statement on page 1222 in THE LANCET of Dec. 8th, 1928, made at a meeting of the Osler Club last July, "when Osler was professor of medicine at Harvard," should, of course, be "when Osler was professor of medicine at Johns Hopkins University." That the statement is merely a slip on the part of the speaker is shown by the immediate reference to Baltimore. That Osler could have gone in 1909 to Boston as medical adviser of the then new hospital on the Peter Bent Brigham Foundation is a well-known fact among his friends.[1]

The following incident has never appeared in print, and may be put on record in this connexion: In January, 1894, I was editing the *International Medical Magazine*, started as a companion monthly to the quarterly *International Clinics*, of which the 152nd volume has just been gotten out under my editorship, and I decided to report for its pages [2] a special meeting of the College of Physicians of Philadelphia called for Jan. 12th, 1894, with the object of discussing the subject of the proposed action of the Board of Health of Philadelphia in reference to the registration of patients suffering from tuberculosis. In the innocence of my then young medical life I invited the professor of bacteriology in the Woman's Medical College of Philadelphia and a few medical students of my class in pathology at the University of Pennsylvania to attend the meeting, and such was the fame of the former clinical professor of medicine in that institution of learning, then at Johns Hopkins University in Baltimore, that instead of a few students—the invitation had been passed on from mouth to mouth—they seemed like the sands of the sea in number when I entered the room and found the one lone female, my assistant at St. Clement's Dispensary, and the students occupying all available seats, thus making many of the Fellows to stand. Dr. Weir Mitchell was in the chair, and on opening the meeting called the secretary to him and requested that he read from the by-laws the section covering the admission of strangers to the meetings of the College, which required that this be done by a viva voce introduction at the time of the meeting. The professor was properly introduced by name, and "some medical students" covered the remainder, some of whom by this time having seen the propriety of surrendering their seats to Fellows. I can still recall the consolation which I got out of Osler's evident enjoyment of the, to me, embarrassing situation.

At this meeting Osler was one of the few physicians present advocating the making of the reporting of all open cases of tuberculosis mandatory, but the resolution of the Council of the College that this should not be done, was passed. At the time Dr. Osler kindly sent me the following outline of his remarks for publication[3]:—

First.—Following a primary law of parasitism, the bacillus tuberculosis frequents chiefly that organ in its host which communicates most freely with the exterior. Just as countless thousands of ova are thrown off from the intestine of the bearer of a tapeworm, so from tuberculous lungs in a state of softening and cavity-formation, countless millions of bacilli are cast out daily with the sputum.

Second.—The widespread diffusion of the parasite outside of the body has been demonstrated in the infectiveness of the dust and of the scrapings of the walls of rooms and wards occupied by patients with pulmonary consumption. Moreover, the greater prevalence of tuberculosis in crowded communities, the enormous mortality from the disease in prisons and institutions, and its frequent occurrence as a house malady, suggest that the conditions favouring its continuance are those which foster the growth and spread of a specific contagion.

Third.—In the language of parasitology the lungs constitute the chief seat of election. But, apart also from gross pulmonary lesions, the proportion of autopsies in which the bronchial glands are found tuberculous speaks unmistakably for direct infection in the existence of their function as dust filters.

On these grounds I believe that the registration of pulmonary tuberculosis would be beneficial—enforcing attention to those sanitary details so apt to be slighted or overlooked, and diminishing directly the danger of contagion in the community.

Infection through food is closely related also to the endemic prevalence of tuberculosis. The incidence of the disease in the mesenteric glands of infants indicates that the gastro-intestinal canal is a portal of infection only a little less wide than that of the respiratory tract.

The question of tuberculosis is not, however, settled with the disinfection of the sputa of consumptives.

The hereditary transmission of the disease must be accepted, though an estimate of the frequency of this mode of infection must necessarily be uncertain, but for certain forms Baumgarten's theory of latency is particularly suggestive. Tuberculosis has been well called the *pébrine* of the human race. The analogy is striking, for not only, as you will remember, is the parasite of the silkworm disease transmitted by direct contagion, but it also infects the eggs, which hatch, and may pass through various stages of development before they are finally destroyed.

Lastly, and here is consolation, the conditions which render individuals more or less immune scarcely yield in importance to those which maintain the vitality of the tubercle bacilli in a community. So widespread is the disease that few of us escape infection,[4] and the statistics of the Paris morgue show that in more than 50 per cent. of adults the germs not only gain an entrance, but actually effect a lodgment. As a factor in tuberculosis, the *soil*, then, has a value equal almost to that which relates to the *seed*, and in taking measures to limit the diffusion of the parasite let us not forget the importance to the possible host of combating inherited weakness, of removing acquired debility, and of maintaining the nutrition at a standard of aggressive activity.

And it is to be remembered that this was written by Osler 35 years ago, within 12 years after the discovery of the tubercle bacillus by Koch.

I am, Sir, yours faithfully,

HENRY W. CATTELL.

THE AIR TRANSPORT OF INVALIDS.

To the Editor of THE LANCET.

SIR,—It may be of general interest to the medical profession to know of the facilities offered by air transport to patients travelling abroad, who by reason of their state of health are unable to stand the strain by the ordinary boat and train routes. In the past we have carried several invalids, including stretcher cases, to various destinations, either on scheduled services or by specially chartered aircraft; in the most recent of these cases we have received a letter from the husband of the patient, who has given us permission to use it in the interest of others, who, no doubt, would like to consider this mode of travel, should they feel that the longer journey by train and boat presents insuperable difficulties. In the particular case under review the patient was suffering from a spinal complaint and was proceeding to a sanatorium at Leysin in Switzerland. The journey was undertaken in the company of her husband and nurse, a bed being provided in the forward portion of the cabin, thus causing no inconvenience to the ordinary passengers on board. The party was carried on an ordinary service aircraft, an additional fare being charged for the patient owing to the extra floor space occupied, the actual flying times being: Depart Croydon, 08.00; arrive Paris, 10.20; depart Paris, 11.10; arrive Basle, 13.58; 485 miles, as against 14 hours, 560 miles by boat and train, quickest route. As there was no aerodrome suitable in the vicinity of Leysin a connexion from Basle was made in a saloon car, in which the patient again travelled in a prone position. Refreshments were supplied en route and at Paris the privacy of the machine was secured for the patient, so that the nurse could attend to her.

From a subsequent conversation we had with the manager of the agency, who dealt with the inquiry in

[4] Osler himself at various times had anatomical warts from the making of antopsies.

the original instance, it is understood that the husband was of the opinion that the comfort and ease of the journey was far superior to that of the alternative routes and that the slight jarring caused when the aeroplane was taking off and landing, although quite perceptible, was never likely to cause any injurious discomfort to the patient.

IMPERIAL AIRWAYS, LIMITED.

Airways House, Charles-street, S.W., Jan. 1st, 1929.

THE ASTHMA RESEARCH COUNCIL.

To the Editor of THE LANCET.

SIR,—In view of statements which have recently appeared in the press to the effect that a "certain cure" for asthma has been found, we, the undersigned, desire to place on record that there is no such "cure" known to medical science and that there is not any one form of treatment which is effective in all cases of asthma.

Investigations are being made under the auspices of the Asthma Research Council and with the approval and support of the Medical Research Council and the Ministry of Health into the mysteries of this distressing complaint which, it is hoped, will lead to a better knowledge of its origin and to the discovery of improved methods of prevention and treatment.

We hope that all interested in the subject, and especially well-to-do sufferers, will give their moral and financial support to the campaign, which will be inaugurated by the Lord Mayor of London at the Mansion House on Jan. 15th, for a national fund to provide research centres at several of the leading London and provincial hospitals, where asthma and its allied diseases will be scientifically and exhaustively investigated. Donations and offers of assistance should be sent to Sir Albert Stern, K.B.E., C.M.G., Hon. Treasurer, Asthma Research Council, London Clinic, Ranelagh-road, London, S.W. 1.

We are, Sir, yours faithfully,

HUMPHRY ROLLESTON,
DAWSON OF PENN,
ARTHUR F. HURST,
F. E. FREMANTLE.

Jan. 11th, 1929.

THE GRANULES OF THE TUBERCLE BACILLUS.

To the Editor of THE LANCET.

SIR,—In your issue of Dec. 29th, 1928, under the above heading, when you favour me by making some criticisms upon my book [1] upon the tubercle virus, you make a mistake which is of importance when you say that the photomicrographs reproduced there were taken with 1/18th immersion lens. These photomicrographs have been taken direct, no enlargements whatever, with the "Davon super microscope" [2] and they are all at a magnification of × 4000 and ×5000, and so far as I am aware they are the first to be published in any book. These have the great advantage that from a morphological point of view they are more reliable than others, and they are therefore worthy of the especial notice of research workers.

I am, Sir, yours faithfully,

WM. C. MINCHIN.

Quarry-road, Hastings, Jan. 4th, 1929.

"HEALTH COLUMNS" IN THE PUBLIC PRESS.

To the Editor of THE LANCET.

SIR,—Where is this promiscuous medical advice in the "health columns" of various journals going to end? In the current number of a certain magazine an amazing amount of advice is given to correspondents which is far beyond the scope of diagnosis and treatment by correspondence. One reader is advised to get treatment, "such as injection of a polyvalent vaccine of staphylococci-streptococci and *Micrococcus catarrhalis*." Another is told to ask her doctor if she might have a course of about twelve injections of arsenic and manganese. A further inquirer is told to ask for injections of glycerophosphates! These are only a few samples of the variety of advice and prescriptions which are proferred. It seems to me that the medical profession should take steps to limit this wanton dealing out of so-called medical help.

I am, Sir, yours faithfully,

HAROLD LONG.

Stormont-road, Highgate, N., Jan. 4th, 1929.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

LOCAL GOVERNMENT BILL.

(*Concluded from p. 52 of last issue.*)

Exemption of Maternity Homes.

Miss BONDFIELD then moved an amendment to remove maternity homes from the operation of the clause, and particularly from the operation of the uniform enforcement of the provision which had just been discussed. She said that the work in connexion with maternal mortality was still in an experimental stage, and anything which shook the present position was bound to act to the detriment of the service. For instance, the psychological effect of making a provision so that the operation of the financial arrangements in regard to municipal maternity centres were on precisely the same lines as those of the poor-law would be a deterrent so far as a great many women were concerned.

Sir KINGSLEY WOOD said that while he agreed as to the importance of making due provision for maternity, and encouraging as many mothers as possible to enter maternity homes, if Miss Bondfield thought that under this clause they were swopping horses and altering the present practice she was greatly mistaken. The provision which was being inserted in the clause generally was already the invariable practice so far as maternity homes, both municipal and voluntary, in this country were concerned. The clause, so far from making any alteration, really set out what was the universal practice of the voluntary maternity hospitals and homes to require that inmates or their relatives should pay what they could for the service. Some 60 or 70 municipal maternity homes recovered appropriate contributions unless they were satisfied, having regard to the circumstances of the inmate, that nothing could be paid. Therefore, there was no ground for saying that there was any alteration in the practice, or for anyone being frightened away from the maternity homes of the country by the application of this clause.

Replying to further debate, Mr. CHAMBERLAIN said that they were faced with the fact that there was not a sufficient number of maternity homes. They wanted more to be provided, but there would be still greater difficulty in getting local authorities to build more maternity homes in future if they were faced with the prospect that when they had built them they were going to be a heavy charge on them because the authority would not be able to recover expenses from patients.

The amendment was negatived by 250 votes to 145.

Definition of Infectious Disease.

Mr. RENNIE SMITH moved an amendment providing that the term "infectious disease" in the clause should be declared to include tuberculous and venereal disease.

Sir KINGSLEY WOOD said that the Ministry had placed the amendment before their legal advisers, and they had stated that both tuberculosis and venereal disease could be regarded as coming within the meaning of the clause relating to infectious diseases, and that the amendment was therefore unnecessary.

Dr. VERNON DAVIES said that the Ministry of Health was taking a rather important step. If they were to say that the term infectious diseases was to include, in all cases, tuberculosis and venereal disease, how were they going to keep out infantile paralysis, encephalitis lethargica, and influenza?

The Chairman pointed out that the Minister had merely stated that these words as a matter of definition would include certain complaints.

Sir H. SLESSER said that there was no definition at all of infectious disease in the Bill. Sir Kingsley Wood had said that he was advised the the term infectious disease included tuberculosis. The position was very unsatisfactory. He wanted to know where the Committee stood in the matter of definition. Was there no Act that defined infectious disease? If so, the Bill ought to be redrafted so as to say that the words "infectious disease" here had the meaning attached to them in some other Act. Or did the right hon. gentleman mean that as a question of medical fact infectious disease included these particular things?

Sir T. INSKIP (Attorney-General) said that the Committee never needed legal arguments if a little common sense would solve the problem. Fortunately, most of them understood the English language, and the words "infectious disease" were not a term which lawyers used and which required an interpretation Act. They were words which meant that a disease was infectious and, that so long as people suffering from it were at large, might result in injury to other persons. The result was that people who suffered from what were, in fact, infectious diseases were required in the public interest to go into an institution for treatment. The question was, what were in fact infectious diseases? Everyone agreed that tuberculosis and venereal diseases were, in fact, infectious diseases. Then the question was as to whether some other diseases were not infectious diseases. They would not arrive at a solution of this question merely by putting in the words "tuberculosis and venereal disease," because by including some words they tended to exclude others. It was better to leave the question of what was an infectious disease to be solved by proper evidence of fact, if ever such a question arose; and he had very little doubt that those questions of fact would be solved by the common sense of the doctors and authorities without any necessity to resort to a court of law.

Lieut.-Colonel FREMANTLE said that he dissented from the reading which the Attorney-General had just given. He could foresee his colleagues of the medical profession having to administer this measure, and they must know what cases they were dealing with, and what cases they were not dealing with under it. In the ordinary terminology of public health, the phrase "infectious disease" had a definite meaning. It was defined by an Order of the Ministry of Health interpreting certain Acts of Parliament in relation to infectious diseases. There was a specific catalogue of the diseases which were included in this definition. It was easy to administer a measure of this kind on those lines, but if his hon. and learned friend had the good fortune to belong to the medical instead of the legal profession, and if he, as a medical officer, had to try to work the administration of Acts relating to infectious diseases on the lines which he himself had suggested, he would find it an impossible task. They must have it laid down what diseases were to be regarded as infectious diseases. For practical purposes, venereal disease was not called an infectious disease, and certainly nobody had ever suggested that cancer was an infectious disease. He (Colonel Fremantle) suggested that the Minister of Health might reconsider this question in order to insert in the definition clause something defining the words "infectious disease" as being definitely associated with the term as generally interpreted in other Acts.

Sir KINGSLEY WOOD, after further discussion, said it was not a question of his own opinion but of fact as to whether a disease was infectious or not. If his own opinion was of any value he should say certainly tuberculosis would be included, but that was only his opinion. The advice given to the Department was that the amendment was unnecessary.

The amendment was negatived by 258 votes to 145. Under the guillotine resolution the clause was agreed to by 270 votes to 147. Clauses 18 to 27 in Part II. of the Bill were afterwards agreed to on a division under the guillotine, without discussion. Clause 18 provides for the transfer of the functions of the guardians under the Registration Acts to the county councils and county borough councils. Clause 21 provides that the councils shall prepare schemes for the administration of the Registration Acts, and Clause 23 amends the law in regard to the method of giving information of birth or death. Clause 24 applies this part of the Act to London with certain modifications. In Part III. of the Bill, Clause 26 deals with roads and town planning. After Clause 28 had been passed, dealing with the transfer of classified roads in urban districts to the county council, the Committee stage was adjourned until the following day.

Medical News.

UNIVERSITY OF LONDON.—At recent examinations the following candidates were successful:—

M.D.

Branch I. (Medicine.)—Susanna M. Bernard and Kathleen M. Bowman-Manifold, London (R.F.H.) School of Medicine for Women; J. W. Brown, Middlesex Hosp.; W. F. Gaisford, St. Bart.'s Hosp.; Lazarus Hartston, London Hosp.; *Horace Joules, Middlesex Hosp.; Maurice Mitman, Guy's Hosp.; H. S. Morley, Univ. Coll. Hosp.; Marie Pedersen, and Muriel F. Prout, London (R.F.H.) School of Medicine for Women; W. E. Rees, St. Thomas's Hosp.; B. B. Sharp, St. Bart.'s Hosp.; A. S. Wesson, Univ. Coll. Hosp.; and W. S. Whimster, Guy's Hosp.

* University Medal.

Branch IV. (Midwifery and Diseases of Women.)—R. K. Ford, London Hosp.; M. E. MacD. Jago, Guy's Hosp.; Lucy Parker, London (R.F.H.) School of Medicine for Women; and H. W. Parrott, London Hosp.

Branch VI. (Tropical Medicine.)—A. N. Kingsbury, Middlesex Hosp. and London School of Tropical Medicine; and J. N. Leitch, St. Bart.'s Hosp. and London School of Tropical Medicine.

At a meeting of the Senate on Dec. 19th, 1928, it was resolved to institute a university chair of anatomy tenable at St. Thomas's Hospital Medical School.

The degree of Ph.D. (Biochemistry) was conferred on William James Griffiths, of St. Thomas's Hospital, for a thesis on Gastric Secretion.

Forthcoming Lectures.—The following lectures will be delivered, unless otherwise stated, at University College, Gower-street, London: Three on the Hygiene of the Mercantile Marine, by Dr. J. Howard-Jones, M.O.H. for Newport, at 5.30 P.M. on Fridays, Feb. 22nd and March 1st and 8th; three on the Properties of, and Methods of Estimating, some Therapeutic Agents, by Dr. J. H. Burn, at 5 P.M. on Feb. 27th and 28th, and March 1st; six, with demonstrations, on Cytology in Relation to Physiological Processes, by Dr. R. J. Ludford, at 5 P.M. on Thursdays from Jan. 24th to Feb. 28th; three on Fatigue, by Dr. G. P. Crowden, at 5 P.M. on Mondays, Jan. 14th, 21st, and 28th; six on the Physiology of Reproduction, by Mr. A. S. Parkes, D.Sc., at 5 P.M. on Wednesdays, Jan. 16th to Feb. 20th; ten on Comparative Physiology, by Mr. C. F. Pantin, at 5 P.M. on Fridays, Jan. 18th to March 22nd; three (in English) on Some Questions of Tropical and Local Helminthology, by Prof. F. Fülleborn, of Hamburg, at 5.30 P.M. on March 11th, 12th, and 13th, at the London School of Hygiene and Tropical Medicine; and three on the Eye in General Medicine, by Dr. A. Maitland Ramsay, at 5.30 P.M. on March 4th, 6th, and 8th, at University College Medical School.

A course of public lectures on the Current Work of the Biometric and Eugenics Laboratories will be given at University College at 5.30 P.M. on Tuesdays, from Jan. 29th to March 5th. The lecturers will be Prof. Karl Pearson, F.R.S., Dr. Julia Bell, Mr. G. M. Morant, D.Sc., Miss Ethel Elderton, and Dr. Percy Stocks. The lectures will be open to the public without fee.

ROYAL MICROSCOPICAL SOCIETY.—The annual meeting of this society will be held in the Lecture Hall at 20, Hanover-square, London, W., on Wednesday, Jan. 16th, at 7.45 for 8 P.M., when Mr. Joseph Barnard, F.R.S., will deliver a presidential address on Some Aspects of Ultra-Violet Microscopy.

BRITISH INSTITUTE OF PHILOSOPHICAL STUDIES.—At 18, John-street, Adelphi, London, W.C., on Tuesday, Jan. 15th, at 8.15 P.M., Mr. Roger Fry will lecture on Representation in Art.

COMMITTEE ON OCCUPATIONAL DISEASES.—The fourth meeting of the Permanent International Committee on Occupational Diseases will open at Lyons on April 3rd. The chief subjects of discussion will be Silicosis, Cataract of Occupational Origin, and the Endocrine System and Poisonings. Those desirous of taking part in the meeting must be introduced by a titular member of the committee or by the executive or the Organising Committee. The secretary is Dr. Mazel, 54, avenue de Noailles, Lyons.

ASTLEY-AINSLIE INSTITUTION.—The governors of this Edinburgh institution have appointed Lieut.-Colonel John Cunningham, I.M.S., to be its medical superintendent. Colonel Cunningham, who is a son of the late Prof. D. J. Cunningham, professor of anatomy in the University of Edinburgh, graduated M.B. Dub. in 1904, and is at present director of the King Institute of Preventive Medicine, Guindy, Madras. He was formerly assistant director of Central Research Institute, Kasauli. He has contributed various articles on clinical medicine to medical publications. He will take up his duties in the spring of this year, when the extended buildings will be completed.

THE death is announced of Dr. Maurice E. J. L. Letulle, sometime professor of clinical medicine in the University of Paris, at the age of 75. Prof. Letulle had been a member of the Academy of Medicine since 1908, and was the author of several standard works on pathological and clinical subjects.

OPTICAL SOCIETY.—A meeting of this society will be held at the Imperial College of Science and Technology, South Kensington, at 7.30 P.M., on Thursday, Jan. 17th, when a paper on the Function of the Lens Capsule in the Accommodation of the Eye will be read by Mr. E. F. Fincham, and papers on a Double Reflexion Level and Photographs of Reflexion Caustics by other members.

SOCIETY OF M.O.H.'S AND MEDICO-LEGAL SOCIETY. A joint meeting of the Medico-Legal Society and the Maternity and Child Welfare Group of the Society of Medical Officers of Health will be held at 8.30 P.M. on Thursday, Jan. 24th, at 11, Chandos-street, London, W, with Sir William Willcox, president of the Medico-Legal Society, in the chair. A discussion on Criminal Abortion and Measures Necessary to Restrict the Sale of Abortifacient Drugs will be opened by Dr. F. J. McCann, Dr. R. A. Lyster, Sir Bernard Spilsbury, Mr. H. Beckwith Whitehouse, and Mr. H. D. Roome. Members of either Society may introduce guests to the meeting.

POST-GRADUATE COURSES AT ROYAL NORTHERN HOSPITAL.—As announced last week a series of courses on special subjects will begin at this hospital on Jan. 28th. The first course on Gastro-enterology starts on this date, and during the subsequent fortnight 14 lectures will be devoted to the medical, surgical, radiological, and pathological aspects of the subject. It will be treated primarily from the standpoint of the practitioner. Applications, together with the fee of £2 2s., should be lodged with the Secretary of the hospital (Holloway-road, London, N. 7), not later than Jan. 21st. If there are less than six applicants applying no course will be held. Detailed programmes of this and other courses may be had from the Dean.

ORDER OF ST. JOHN OF JERUSALEM.—The following promotions and appointments have been made: Colonel Sir James R. A. Clark, Bailiff Grand Cross, from Knight of Justice; Colonel J. A. Dick and Dr. C. C. Lavington, commanders; Major F. Howard Humphris, Dr. A. G. Osborn, Dr. W. E. Thomas, Lieut.-Colonel Sir George W. Badgerow, Sir Percival Horton-Smith Hartley, and Sir Wilfred T. Grenfell, officers; Dr. J. R. Summers Park, Dr. James Pirie, Dr. Charles H. Perram, Dr. H. J. Ley, Dr. J. A. MacKenzie, Dr. William Megaw, Dr. J. R. H. Dubourg, Dr. John Orr, Dr. William Arnott, Dr. A. Oliver Holbeche, Dr. Christopher Armstrong, and Dr. John M. Wilson, Serving Brothers; and Dr. Simon Simons, Associate Serving Brother.

UNIVERSITY OF GLASGOW.—Prof. Andrew Hunter, of Toronto, has been appointed to the Gardiner Chair of Physiological Chemistry, rendered vacant by the promotion of Prof. E. P. Cathcart to the Regius Chair of Physiology.

Graduating M.B. with first-class honours at the University of Edinburgh in 1901, Dr. Hunter carried out post-graduate work at Berlin and Heidelberg, and after working for a time in Edinburgh was appointed assistant professor of biological chemistry at Cornell University, U.S.A. Later he was appointed to the chair of biological chemistry in the University of Toronto. He is expected to take up residence in Glasgow early in the New Year. His colleague at Toronto, Prof. J. J. R. Macleod, F.R.S., was recently appointed to the Regius chair of physiology at Aberdeen.

PEOPLE'S LEAGUE OF HEALTH.—On Jan. 18th this League will begin a series of 12 Sims Woodhead health lectures. The lectures will be given weekly at the rooms of the Medical Society of London, 11, Chandos-street, W., at 6 P.M., the subjects and speakers being as follows:—Jan. 18th: The Need for a National Stocktaking, Mr. C. J. Bond; 25th: Bones, Muscles, and Internal Organs, Prof. H. E. Roaf; Feb. 1st: Glands, Circulatory, and Respiratory Systems, Prof. M. S. Pembrey, F.R.S.; 8th: Brain and Nervous System, Sir Robert Armstrong-Jones; 15th: Lymphatics, Lymphatic Glands, and Digestive System, Prof. B. Collingwood; 22nd: Nutrition and Protective Foods and Excretory System, Prof. V. H. Mottram; March 1st: Human Faculties, Dr. Thomas Beaton; 8th: Water, Air, Light and Ventilation, Dr. Leonard Hill, F.R.S.; 15th: Growth and Development of Mind and Body, Dr. R. D. Gillespie; 22nd: Youth, Adolescence, and Adult Life, Mr. Z. F. Willis; April 12th: Natural Capacity and Health in Relation to a Career, Sir Thomas Oliver; 19th: Decay and Disease, Natural and Premature, Dr. C. C. Worster-Drought. Full particulars may be had from the headquarters of the People's League of Health, 12, Stratford-place, London, W. 1.

THE death is announced of Miss Caroline Helen Keer, R.R.C., late matron-in-chief of Queen Alexandra's Imperial Military Nursing Service, at the age of 71. She was the second daughter of Major-General Keer and joined the Army Nursing Service in 1887.

VICTORIA INFIRMARY, GLASGOW.—A new departure in connexion with hospital treatment in Glasgow is contemplated by the governors of the Victoria Infirmary, who intend to erect an annexe to their establishment for the accommodation of paying patients. Costing about £25,000 the new structure will have accommodation for some 30 patients, but provision will be made for further extensions. Patients of the annexe will receive the same treatment as is given in the ordinary wards, and will be asked to pay six guineas per week, inclusive, for the first three weeks and half that charge per week thereafter.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—A new series of demonstrations will be given at the Wellcome Museum of Medical Science, 33, Gordon-street, London, W.C., on Wednesday, Jan. 16th at 4.30 P.M., when Dr. Helen Mackay will speak on Some Recent Work on Rickets. No fee will be charged for this demonstration. A new series of lectures, entitled Pitfalls in Medicine and Surgery, will start on Monday, Jan. 21st at 5 P.M., at the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, with a lecture by Dr. Robert Hutchison on Pitfalls in Diagnosis of Dyspepsia. The weekly demonstrations in medicine and surgery will be resumed shortly at the various London general and special hospitals. A full list of lectures and demonstrations for the next three months may be had on application. Two courses begin on Jan. 14th and continue for two weeks. These are an intensive course in cardiology at the National Hospital for Diseases of the Heart, and an all-day course at the Queen's Hospital for Children. From Jan. 28th to Feb. 9th an intensive course in medicine, surgery, and the specialties will take place at the Prince of Wales's General Hospital, Tottenham. On Tuesdays and Saturdays, at 11 A.M., from Jan. 29th to Feb. 23rd, a series of lecture-demonstrations in psychological medicine will be given at the Bethlem Royal Hospital by Dr. Porter Phillips and members of the staff. Copies of all syllabuses and information about the general course arranged by the Fellowship may be had from the Secretary at 1, Wimpole-street, W. 1.

THE death is reported of Dr. Johannes von Kries, for many years professor of physiology in the University of Freiburg in Breisgau. He was best known as a physiologist by his many interesting experiments to elucidate the phenomena of colour vision and by his studies on physiological optics. With his brother he worked in C. Ludwig's laboratory in Leipzig in the 'seventies. He devised ingenious direct experiments confirming and extending the observation of Arago that certain small stars, which are visible at the periphery of the retina by indirect vision, are not visible by direct vision—i.e., when their image falls on the fovea centralis. He extended the "duplicity theory" of Max Schultze, that the cones of the retina subserve light and colour perceptions, while the rods are concerned with the perceptions by light, but are incapable of initiating colour sensations. The observations of Parmaud and more especially those of von Kries gave a wider basis to Max Schultze's theory—founded on his classical microscopic observations—on the structure of the retina in 1866, as to the distribution of the rods and cones in the retina of man and animals. Von Kries assumed that the rods act as the receptors in scotopic or twilight vision, while the cones, particularly those of the fovea, are the organs of photopic vision.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Jan. 15th.—5 P.M., MEDICINE. Dr. F. Parkes Weber: Endocrine Tumours. Dr. O. Leyton: How Can we Decide that a Case of Glycosuria should be Treated. The papers will be followed by discussions. 5.30 P.M., GENERAL MEETING OF FELLOWS. Ballot for election to the Fellowship. 8 P.M., PATHOLOGY. Communications: H. Warren Crowe: The Experimental Production of Foci of Infection in Rabbits and its Bearing on Osteo-arthritis. B. J. W. Jervis and R. B. Bourdillon: Treatment of Experimental Anæmias with Ultra-violet Light. Demonstrations: W. G. Barnard: Secondary Carcinoma Infiltrating a Uterine Fibroid. W. D. Newcomb: Carcinoma of Small Intestine.

WEDNESDAY.—5 P.M., SURGERY: SUBSECTION OF PROCTOLOGY. Clinical Pathological Meeting.
THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) Dr. J. H. T. Davies: (1) Pigmentation of the Face—for Classification. (2) Case for Diagnosis—? Fox-Fordyce Disease. Other cases will be shown.
FRIDAY.—8 P.M., PATHOLOGY, SURGERY, OBSTETRICS. Special Discussion on Post-operative Thrombosis. Openers: W. Howel Evans (Pathology), D. H. Patey (Surgery), Victor Bonney (Obstetrics). 8.30 P.M., ELECTRO-THERAPEUTICS. Papers: Mr. C. Thurstan Holland: Epiphyseal Injuries of the Wrist-joint. Dr. R. S. Patterson: Some Factors Influencing Epiphyseal Growth and Union.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, Jan. 14th.—8 P.M., Pathological Evening.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, W.
THURSDAY, Jan. 17th.—8.15 P.M., Mr. Edward Hindle, Ph.D.: An Experimental Study of Yellow Fever. Chairman: Prof. J. W. W. Stephens, F.R.S. (Preceded at 7.45 P.M. by a demonstration of microscope slides and specimens to illustrate the subject.)

CHELSEA CLINICAL SOCIETY.
TUESDAY, Jan. 15th.—8.30 P.M., at St. George's Hospital. The following will show cases or specimens; Mr. L. Abel, Mr. Ivor Back, Dr. H. MacCormac, Dr. J. Moore, Dr. Orlianski, and Dr. C. Sundell.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, Jan. 14th, to SATURDAY, Jan. 19th.—WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed., at 4.30 P.M., Dr. Helen Mackay: Some Recent Work with Regard to Rickets. No fee. NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W. Intensive Course in Cardiology, lasting two weeks. QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, E. All-day Course for two weeks. Further information from the Secretary.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
MONDAY, Jan. 14th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.
TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.
THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.
FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
TUESDAY, Jan. 15th.—5 P.M., Dr. A. C. Roxburgh: Eruptions Due to Physical Causes.
THURSDAY.—5 P.M., Dr. J. M. H. MacLeod: Ringworm Infections.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.
MONDAY, Jan. 14th.—1.30 P.M.: Methods of Examination and Diagnosis Courses. Mouth and Pharynx.
WEDNESDAY.—1.30 P.M.: Larynx.
FRIDAY.—4 P.M., Dr. Dan McKenzie: Early Mastoid Operations.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.
TUESDAY, Jan. 15th.—3.15 P.M., Dr. A. Lisle Punch: Demonstration of Chest Cases.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURE, Manchester.
FRIDAY, Jan. 18th.—4.30 P.M. (at the Whitworth-street West Branch), Dr. Lacey: Ante-partum Hæmorrhage.

SHEFFIELD UNIVERSITY POST-GRADUATE CLINICS.
FRIDAY, Jan. 18th.—3.30 P.M. (at the Royal Hospital), Prof. Hall: Clinical Cases.

Vacancies.

For further information refer to the advertisement columns.

Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150
Brighton, Royal Sussex County Hospital.—Jun. Asst. Pathologist. £250. Also Hon. Medical Clinical Asst. Also H.S. £150.
Cape Town University.—Asst. in Pathological Chemistry. £800.
Cardiff City Mental Hospital, Whitchurch, near Cardiff.—Med. Supt. £1000.
Cardiff, Royal Infirmary.—Three H.S.'s. Also Three H.P.'s. Each at the rate of £50.
Chester, Royal Infirmary.—Third Hon. Surgeon.
Exeter City Mental Hospital.—Asst. M.O. £350.
Exeter, Royal Devon and Exeter Hospital.—H.S. Also Asst. H.S. At rate of £130 and £100 respectively.
Great Yarmouth, General Hospital.—H.S. £150.
Hospital for Sick Children, Great Ormond-street, W.C.—Res. Med. Supt. £300. Also Anæsthetist. 15 gns.
Ilford Emergency Hospital, Ilford, Essex.—Jun. H.S. £100.
Leicester Royal Infirmary.—Surgical Dresser. 10s. 6d. weekly.
Leigh Infirmary, Lancashire.—Res. H.S. At rate of £150.
Liverpool, Royal Liverpool Children's Hospital, Myrtle-street.—Res. Cas. O. £120. Also Two Res. H.P.'s and Two Res. H.S.'s. Each at rate of £60. Also Res. M.O. for Heswall Branch. At rate of £120.
L.C.C., Mental Hospital Service.—Eighth Asst. M.O. £300.
London Hospital, E.—Dental Anæsthetist.
London Temperance Hospital, Hampstead-road, N.W.—Med. Reg. 40 guineas.
Malayan Medical Service.—Medical Officers. £700 per annum.
Manchester, Ancoats Hospital.—Res. M.O. £150.
Manchester, St. Mary's Hospitals.—Four H.S.'s. Each at rate of £50.
Marseilles, Queen Alexandra Memorial Hospital.—Res. M.O. At rate of £150.
Northampton General Hospital.—Hon. Pathologist.
Nottingham, City Mental Hospital.—Jun. Asst. M.O. £350.
Oldham, Royal Infirmary.—H.S. At rate of £175.
Paddington Green Children's Hospital, W.—Two Hon. Surgeons.
Portsmouth, Royal Portsmouth Hospital.—Cas. O. At rate of £100.
Princess Louise Kensington Hospital for Children, N. Kensington. H.S. At rate of £75.
Queen's Hospital for Children, Hackney-road, E.—Asst. Surg.
Reading, Royal Berkshire Hospital.—Hon. Asst. Physician.
Rochdale Infirmary and Dispensary.—Jun. H.S. £175.
Royal Army Medical Corps.—Twenty-five Commissions. £500 to £2000.
St. Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.
St. Marylebone General Dispensary, 30, Marylebone-lane, W.—Clin. Asst. in Ultra-violet Radiation Department.
Sheffield Royal Hospital.—Ophth. H.S. Also Res. Anæsthetist. Each at rate of £80.
South-Eastern Hospital for Children, Sydenham, S.E.—Asst. Res. M.O. Honorarium £75.
Stoke-on-Trent, North Staffordshire Royal Infirmary, Hartshill.—Hon. Asst. Physician.
Wallasey, Victoria Central Hospital.—Jun. H.S. £100.
West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Sen. H.P. Also Jun. H.P. At rate of £150 and £100 respectively.
West London Hospital, Hammersmith-road, W.—Aural and Ophth. H.S. and Res. Asst. Cas. O. At rate of £100.
Whipps Cross Hospital, Whipps Cross-road, Leytonstone, E.—Anæsthetist. £200. Also Specialist Consultants. Special Fees.
Willesden General Hospital.—Clinical Assistants.
Wrexham and East Denbighshire War Memorial Hospital.—Two Res. H.S.'s. Each at rate of £150.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Roade (Northants) and at Lockerbie (Dumfriesshire).

Births, Marriages, and Deaths.

BIRTHS.

LLOYD.—On Jan. 2nd, at Hereford-square, Kensington, the wife of Eric I. Lloyd, F.R.C.S., of a son.
OSBOURNE.—On Jan. 5th, at Watford, Herts, the wife of Denis Osbourne, M.B., Ch.B., of a daughter.
STRUTHERS.—On Jan. 2nd, the wife of J. A. Struthers, M.B., M.R.C.P., of Fortune Green-road, N.W., of a son.
VINES.—On Jan. 5th, at Wyndyate, Chalfont St. Peter, Bucks, the wife of H. W. C. Vines, M.D., of a son.

MARRIAGES.

KERLEY—MCNAMEE.—On Jan. 2nd, at University Church, Dublin, Dr. Peter Kerley, Weymouth-street, London, to Olivia McNamee, Enniskillen.
WALLACE—BEVINGTON.—On Jan. 1st, quietly in London, Lieut.-Colonel John Wallace, R.A.M.C.T., to Margaret Chieslie (Madge) Bevington.

DEATHS.

BOYS. — On Jan. 7th, at St. Peter's-street, St. Albans, Arthur Henry Boys, M.R.C.S., L.R.C.P., aged 77.
COOK.—On Jan. 1st, of pneumonia whilst on a visit to his son at Isleworth, Joseph B. Cook, M.R.C.S. Eng., L.R.C.P. Edin., of Parkdene, Great Missenden, Bucks, in his 81st year.
DOUGLAS. — On Dec. 31st, 1928, at Mundesley, Norfolk, Arthur McDonald Douglas, M.B., Ch.B., in his 31st year.
RUSSELL.—On Jan. 2nd, at St. Mawes, Wilfred Alan Russell, M.B. Camb., M.R.C.S., L.R.C.P., late R.A.M.C., of the Little House, Mayford, Surrey.
WRIGHT.—On Jan. 4th, at Lennox-mansions, Southsea, from pneumonia, John Lister Wright, M.R.C.S.E., L.R.C.P.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

INDEX TO "THE LANCET,"
VOL. II., 1928.

THE Index and Title-page to Vol. II., 1928, which was completed with the issue of Dec. 29th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

Notes, Comments, and Abstracts.

IODINE IN RELATION TO GOITRE.*

By D. W. CARMALT-JONES, M.D. LOND., F.R.C.P. LOND.,

PROFESSOR OF SYSTEMATIC MEDICINE, UNIVERSITY OF OTAGO, NEW ZEALAND; CONSULTING PHYSICIAN, WESTMINSTER HOSPITAL.

PART I.

IODINE was discovered by Courtois in 1812. Its distribution in air, water, soil, food, and elsewhere was very fully worked out by Chatin between 1850 and 1860. This must have been very remarkable work, the quantities in which the element is present in most substances in Nature is exceedingly minute, and very accurate colour tests are required for its estimation, but in a recent survey by von Fellenberg, a Swiss chemist, Chatin's results were confirmed in almost all particulars. In all physiological and pathological relations a recognition of the minute quantity involved is essential to the comprehension and correct handling of the problems.

Iodine is constantly present in the mammalian thyroid gland. This was first demonstrated by Baumann in 1896, since when much study has been devoted to the association between the two. Oswald (1901) showed that it was present in the colloid portion, and a few years later (1909) Marine and Lenhart established a kind of corollary to this, and showed that the amount of iodine in any thyroid varied inversely with the amount of hyperplasia. Marine and Rogoff (1916), by perfusion experiments into a dog's vein, demonstrated the remarkable affinity of the thyroid for iodine. Fifty milligrammes of potassium iodide injected into a dog's vein increased the iodine content of the thyroid by several hundred per cent. within five minutes. It is highly probable that the internal secretion of the thyroid gland contains iodine, and in 1916 Kendall claimed to have isolated this hormone in crystalline form with an empirical formula showing the presence of iodine; he called this body "thyroxin." More recently Harrington has isolated another body which most physiologists are more willing to accept as representing the thyroid hormone. Iodine therefore appears to be an essential element in the internal secretion of the thyroid gland, and as such is essential to health, since the removal of the thyroid is followed by grave results to many vital processes. The thyroid gland is known to have many important functions, one of which is the control of the basal metabolic rate (B.M.R.). This is of great experimental importance, since the rate is capable of measurement. In myxœdematous patients and cretins, in whom the thyroid gland is either atrophied or hypoplastic and so contains little colloid or iodine, the B.M.R. is low, and in cases of Graves's disease, in which the thyroid is much enlarged and which can be successfully treated by partial removal of the gland, the B.M.R. is high. It is therefore assumed that in cretins the secretion of the iodine-containing thyroid hormone is inadequate, and in cases of Graves's disease it is excessive. Further, the B.M.R. is assumed to be a measure of the secretion of thyroxin. There are thus very good grounds for the view that the activity of the thyroid gland is essentially concerned with the metabolism of iodine.

If iodine is introduced into the circulation it is rapidly taken up by the thyroid, as Marine and Rogoff showed, and the total amount of iodine in the normal thyroid is estimated at between 1 and 2 mg. per gramme of dried substance, with a total of 25 mg. for the whole gland. The amount of iodine in the normal thyroid is thus about 0·1 per cent. of dried substance, and it is further estimated that 10 mg. of iodine must be ingested per annum to maintain this concentration. This supply must be derived from food and water, and the amount present in either of them is exceedingly minute. There is very little in meat, so that the amount in the circulating blood is likely to be very small. The point requires emphasis, because the whole problem of iodine in relation to goitre depends upon the extremely minute quantity of iodine which is commonly required and commonly available for the activities of the thyroid gland. This may be more fully grasped if a comparison is made between the physiological status of sodium chloride and that of iodine in the animal body, with a brief consideration of the development of the vertebrate mammal from the invertebrate marine animal.

* Being the substance of a lecture delivered at the Institute of Pathology and Research at St. Mary's Hospital. Part II. will appear next week.

The latter has an excretory system which communicates directly between the body cavity and the surrounding sea-water, consequently the saline constituents of the body fluid are identical with those of sea-water. Sea-water contains 3·5 per cent. of salts, of which the great majority is sodium chloride, and 0·000002 parts per cent. of iodine, or, in the usual way of describing such minute amounts, 2 parts per 10^7. Vertebrate mammals, derived originally from marine invertebrates, retain a body fluid of similar saline constituents to those of sea-water, but diluted about five times: thus the sodium chloride content of the body fluid is about 0·75 per cent. If the same holds good of iodine, the content of the body fluid should be about 4 parts to 10^7. Whatever, therefore, the actual iodine content of the thyroid gland, the amount which it puts into circulation seems to be exceedingly minute. It is well known that land animals require sodium chloride, derived from some marine source, to be added to their food, and that it is a regular addition to the diet of civilised man. It is therefore easy to understand that if the essential minute amount of iodine is not present in natural food it must be deliberately added. The sea is not, however, the common source of iodine as it is of sodium chloride: in most countries an adequate amount is present in the soil, where it appears to be derived chiefly from igneous rocks. At the same time it is obtainable from the sea, and eaters of sea-fish, particularly of shell-fish, ingest iodine in relatively large amounts. Iodine is present in soil, from which it is taken up by vegetables, and it is from these that animals derive it. Animal food, whether milk or flesh, which has been raised on vegetables with a sufficient iodine content is itself a source of iodine. But the amounts actually present both in soil and food are exceedingly minute. The content of iodine in soils is measured in parts per 10 million (10^7), which is approximately the same as measuring the number of grains to the half ton. The unit of weight commonly employed is the microgramme (Gamma, γ), one-thousandth part of a milligramme, or one-millionth part of a gramme. There are about 60,000 γ to a grain. The iodine content of foodstuffs is measured in γ per kilo, which is the same as parts per 1000 million (10^9). The figures to be quoted are from papers by Hercus, Benson and Carter, and by Hercus and Roberts, and the observations were made on New Zealand material. The richest soil in New Zealand (Taranaki contains 166 parts of iodine per 10^7, and the average content of various foodstuffs, not grown in Taranaki but in several non-endemic districts, is as follows:—

Root vegetables, without skin and unmanured	7	parts per 10^9.
Leafy vegetables, unmanured	24	
White flour	3	
Oatmeal	30	
Beef	13	
Mutton	10	

It is upon the iodine so derived that the thyroid depends for the 10 mg. or 10,000 γ which it requires annually, and which, it will be seen, involves an intake of about 200 γ a week, or about 30 γ a day.

Results of Living on a Soil Deficient in Iodine.

Briefly, it is assumed that the thyroid gland requires 30 γ of iodine daily for its hormone; this iodine it derives from the food, the iodine content of which depends on the presence of iodine in the soil. It is evident that if the soil of any district is deficient in iodine, then the animals which live in the district will be placed at a certain disadvantage in regard to the activities of their thyroid glands. The thyroids, so long as they remain healthy, will attempt to adapt themselves to the conditions in which they are placed, and if they fail to adapt themselves they will show symptoms of disease of one kind or another—that is to say, their functions will be disturbed either by way of excess or defect. It happens that this condition of deficient iodine in the soil is found in many districts in New Zealand, with the result that simple, or endemic, goitre is highly prevalent. This is to be regarded as the response of healthy thyroids to a particular physiological stress. The enlarged gland, however, is unusually vulnerable, and a proportion of the cases become "toxic"—i.e., show to excess the functions of thyroid action, among them an increased B.M.R. Others atrophy, either with or without a toxic period, and show defective thyroid action, up to complete myxœdema, with decreased B.M.R.

These observations were, of course, made in the reverse order from that just given. Goitre has long been observed in New Zealand, and it is only recently that deficiency of iodine in the soil has been recognised as its cause. This discovery is, in fact, the outcome of the most important piece of medical research yet done in the country. Whether the New Zealand results are applicable to other countries where goitre is prevalent I have no means of knowing, but iodine deficiency appears to be the essential cause of New Zealand goitre. Doubtless, with thyroids rendered sensitive by this

means, any of the other numerous causes of goitre may be particularly effective in individual cases. The relation of iodine deficiency in New Zealand has been established by the following steps. Goitre has been prevalent among New Zealand Maoris living in inland districts for as long as tradition goes back. Coastal Maoris, who were and are large fish-eaters, naturally escaped, but in 1925 Hercus found an incidence of 18 per cent. in the only inland tribe so far investigated, the Urewera. In the South Island of New Zealand serious European occupation began between 1840 and 1850, and in 1880 Dr. Hacon, the medical superintendent of the Christchurch Mental Hospital, found a considerable incidence of goitre among his patients and their attendants, and recorded the birth of a child with goitre, and the occurrence of Graves's disease. Hacon attempted to establish the prevalence of goitre throughout the country by means of a questionaire addressed to doctors—a disappointing method—but found at least that there was great variation in the incidence in different parts of the country, Canterbury being then, as now, the most affected district. He published his results in 1892. In 1910 Colquhoun published further observations on similar lines with a spot-map of affected areas. He consulted expert opinion as to the geological character of the districts, but nothing was at that time found which was common to the areas of goitre prevalence.

During the period of the Great War no less than 1500 men out of 130,000 examined were rejected for military service on account of goitre; of these, 1000 were in the Christchurch Military District. Meantime, the importance of iodine to the thyroid gland was gradually becoming established and, in 1916 Drennan, who was familiar with Marine's work, was appointed to the chair of pathology at Otago University. He was at once impressed with the prevalence of goitre as seen in the streets, the hospital, and the post-mortem room, and in 1919 he advised the assay of foodstuffs for iodine, since the conditions in New Zealand appeared to be closely similar to those described by Marine in the Great Lakes district of America. Marine had successfully treated by iodine trout with goitre, pigs born with goitre when the mothers' food was deficient in iodine, and school-girls with endemic goitre. Drennan had found in New Zealand goitrous trout, lambs born with goitre, and a high incidence of goitre among young people. Goitre is to be found in New Zealand among animals both domesticated and wild, among cattle, sheep, horses, and trout; the observations on animals are not yet complete.

The iodine factor in endemic goitre in New Zealand was first seriously investigated by Hercus, who returned to New Zealand after five years' absence during the war, and entered the Public Health Service, which includes the inspection of school-children. He was as impressed as every newcomer with the prevalence of the condition, which rouses little interest in the permanent resident, and he proceeded, with Dr. Eleanor Baker, to investigate the incidence among school-children in Canterbury and Westland. They obtained the remarkable figure of 60 per cent., most of it incipient. These observations were extended by Dr. Baker to the whole country, including some 90,000 persons, and gave a total of 34 per cent. for all children of school age. Great pains were taken by Dr. Baker to secure uniformity in the method of examination and estimation. Many of these juvenile goitres disappear, but it may be noted that many goitrous children have goitrous parents and siblings, and that in the Christchurch Maternity Hospital some 60 per cent. of the mothers are goitrous and 8 per cent. of the babies born have goitre.

There are many supposed causes of endemic goitre, but the only one which Hercus could find applicable to the condition as it occurs in New Zealand is deficiency of iodine in the soil. His attention was first drawn to this as a probable cause by observations made in Canterbury, in the city of Christchurch, and the neighbouring port of Lyttelton, in both of which the water-supply is artesian. The goitre incidence among school-children in Christchurch was 64 per cent., whereas in Lyttelton it was 20 per cent. lower. The Lyttelton water-supply is slightly contaminated with sea-water, and it occurred to Hercus that the trace of iodine so introduced might be responsible for the difference in the goitre incidence, and that in this case the soil was likely to be of greater importance than the water-supply as a source of iodine. This led ultimately to an investigation of the iodine in the soil of the districts throughout the country, together with a record of the goitre incidence in the school-children in the same areas.

INQUESTS IN MANCHESTER.—The number of deaths reported to the city coroner of Manchester in 1928 was 1296, as against 1274 in 1927. 473 inquests have been held, compared with 546 in 1927, the decrease being due to the Coroner's Amendment Act. Under the old Act 612 inquests would have been necessary.

NORTON THE ALCHEMIST.

TRADITION places the beginning of chemical study in Europe in 1144, when Robert of Chester completed his translation from the Arabic of the "Book of the Composition of Alchemy." This science lent itself more than most to knavery, magic, and occultism; but there were honest men among its exponents, and among them we must place Thomas Norton of Bristol.[1] He seems to have been a pupil of G. Ripley, and medical students of to-day, struggling to acquire the rudiments of chemistry, may be heartened to know that Norton apparently learnt the whole science of alchemy in 40 days.

On his return to Bristol, stuffed with alchemical learning, the poor man had no luck. After an auspicious start in which he actually prepared the elixir of gold, he was chagrined at having it stolen by a dishonest servant. He next tried for the elixir of life, which, when prepared, he was most unfortunate in having stolen by a merchant's wife. The latter has been stated, on insufficient evidence, to be the wife of that William Canynges who rebuilt St. Mary Redcliffe. If this be so we can surely pardon the theft, annoying as it must have been to Norton, for as a memorial we have the most glorious parish church in England.

The authorship of the Ordinall is revealed by a curious acrostic; from the first word of the Proeme and the "initiall letters" of the six following chapters we get, with the first line of the seventh chapter, the following lines:—

TO-MAIS-NOR-TON-OF-BRISE-TO
A Parfet Master ye maie him call trowe.

The date of the manuscript is 1477. It has been very well reproduced here, both as to printing and illustrations, and can be commended to all who are interested in an out-of-the-way subject, and quaint diction. We are inclined to wonder whether Butler, in writing "Hudibras," had the Ordinall in mind when he wrote—

"Many rare pithy saws concerning
the worth of astrologic learning."

ACUTE CONGESTION AND ŒDEMA OF THE LUNGS.

ACTIVE congestion of the lungs is regarded by French authors as a primary condition, and is called by them the *maladie de Woillez*. In England and America, on the other hand, it is looked upon as symptomatic, and secondary to cardiac and pulmonary affections. The congestion may be generalised, as, for instance, in some types of cardiac disease or following the inhalation of irritating gases. Local or collateral congestion is seen in many pulmonary diseases such as pneumonia, pleurisy, bronchitis, and tuberculosis—the capillaries in the areas adjacent to the lesions being engorged and distended. As Osler points out, the symptoms of active pulmonary congestion are indefinite and difficult to distinguish from the anomalous or larval forms of pneumonia. The condition is fairly common, especially in children, in whom the only symptoms may be cough and fever persisting for a few days, with physical signs at one of the bases of the lungs of slight impairment of percussion note, distant breath sounds, and a few fine distant inspiratory crepitations. A radiogram of the chest shows at one base, and occasionally at the apex, a characteristic diffuse shadow which clears up as a rule in about one month from the onset. As the illness is usually very mild, the cases rarely, if ever, come to autopsy, and for this reason it is likely that the exact nature of the lesion will remain a subject for controversy.

Dr. G. Caussade and Dr. André Tardieu [2] have made an attempt, by clinical and histological examination of the sputum and lung fluid (withdrawn by exploratory puncture), to obtain some definite evidence by which Woillez's disease may be distinguished from the larval forms of pneumonia. With this in view they studied the symptoms, physical signs, and clinical course of three patients said to be suffering from it, and also carried out careful radiological, chemical, and histological investigations. The clinical pictures of the first two cases described resemble that of atypical lobar pneumonia, but the results of the microscopical and chemical examination of the sputum put the cases, in the author's opinion, definitely into the category of Woillez's disease. The greater part of the microscopic fields, after the specimens had been fixed with dilute chromic acid and stained with Unna's blue, were seen to consist largely of closely packed sero-albuminous droplets, with a few alveolar epithelial cells, polymorphs, streptococci, pneumococci, *Micrococcus catarrhalis*, and *M. tetragenus*

---

[2] Ann. de Méd., 1928, xxiii., 413.

conglomeratus. No red blood cells or tubercle bacilli were seen. On chemical analysis the sputum was found to contain 0·71 per cent. of albumin. In the third patient, owing to the absence of expectoration, the lung fluid was examined, and on microscopical examination numerous sero-albuminous droplets were found, together with red blood cells, occasional polymorphs, and some alveolar epithelial cells in varying stages of hypertrophy and degeneration. Mixed with the latter were dust particles and some macrophages six times as large as a red cell. These macrophages were vacuolated, with an eccentric nucleus and contained partly digested alveolar cells. As all gradations between the alveolar epithelial cells and the macrophages could be seen, Caussade and Tardieu felt justified in assuming that the latter developed from the former. The common factor in all three cases, and in their opinion the characteristic feature of Woillez's disease was the presence of sero-albuminous droplets either in the sputum or in the lung juice. It is a pity that they did not give the results of the microscopical and chemical examination of the sputum of control cases of classical lobar pneumonia, because the absence of sero-albuminous droplets in such cases would have added greater weight to their statements. Again, the possible presence of atypical pneumonia cannot be excluded merely on account of an oscillation of 1° C. in the temperature chart, nor yet because bronchial breath sounds cannot be heard over the affected area, especially when, as in the third case, the absence of sputum is explained by blockage of the air-tubes by fibrinous plugs. If the bronchi are so firmly plugged as to prevent the expulsion of sputum, it seems quite likely that the entry of air into the bronchi would also be stopped and that breath sounds would not be heard over the consolidated area. On the whole it may be said that Caussade and Tardieu have not presented any convincing data by which the *maladie de Woillez* can be differentiated from the atypical pneumonias.

NATURALNESS IN THE SPEECH OF THE DEAF.[1]

THIS Essay is a detailed survey of the lines most likely to ensure success in teaching speech to deaf children. The author has tackled the subject with thoroughness, founding his views on a careful study and comprehensive grasp of the fundamentals of phonetics and voice production. Patient experimentation and years of practical, sympathetic experience render him an authority on the many questions of education, technique, and psychology that are involved.

The promotion of the quality of naturalness of speech in the deaf is of primary importance, for upon their approximately natural and fluent speech depends their ability to communicate with their fellow men. The subdivisions of the Essay show the many-sidedness of the subject dealt with—breathing, voice, speech sounds, accent, phrasing, rhythm, speed, intonation being some of them. To impart an accurate and useful grasp of some or all of these branches to a deaf child is no easy task, and young teachers need all the help obtainable from others of riper experience, gained through study and practice. Mr. Haycock provides a handy book of reference, and the Appendix contains useful exercises in connexion with the subdivisions. The exercises are by way of suggestions, and are open to extension or rearrangement according to the need of the children and feeling of the teacher.

The author stresses the necessity of making use of the natural emotions of pupils, and this is a feature that must not be overlooked. Short exclamatory sentences are invaluable in the cultivation and preservation of good pitch and elastic, rhythmic utterance. The mentalities and dispositions of children vary enormously, but expressions of joy or sorrow, excitement or boredom, like or dislike are common to all and are natural aids in teaching. Artificial aids—e.g., mirrors, a piano, sensitive flame—have their use. Mirrors Mr. Haycock would employ as a corrective; they are easily available and their use is often fascinating to the child. A piano is not so common in deaf schools, but has its uses when available. Deaf children early become sensitive to vibration, and Mr. Haycock puts forward suggestions as to how this can be utilised to correct pitch and intonation. He mentions Dr. Scripture's flame-trainer as of proven value in many cases, but points out that it requires a teacher fully trained and skilful in its use.

The Essay is a real addition to the books helpful in the study and practice of the teaching of speech to the deaf child, and we are not surprised to gather that its author was rewarded with the Braidwood gold medal by the National College of Teachers of the Deaf.

[1] How Best to Promote the Quality of Naturalness in the Speech of the Deaf so as to Ensure Easy Intelligible Oral Intercourse with Those who Hear. An Essay by G. Sibley Haycock. C. G. Goodwin, The Mount, Stoke-on-Trent. 1928. Pp. 60. Post free, 1*s*. 3*d*.

THE KING'S ILLNESS.

OFFICIAL BULLETINS.

(*Continued from p. 58.*)

THE following is the text of the official bulletins which have been issued during the past week and signed by Sir Stanley Hewett, Sir Hugh Rigby, and Lord Dawson of Penn:—

WEDNESDAY, JAN. 2ND. 8.15 P.M.

The King has passed a good day, and there is a slight improvement in His Majesty's condition.

THURSDAY, JAN. 3RD. 11.15 A.M.

The King has passed a restless night and there is no change to report in His Majesty's condition.

8 P.M. The King has had a fair day and there is no change to report in His Majesty's condition.

FRIDAY, JAN. 4TH. 11.30 A.M.

The King has had a quieter night; the local condition shows slight improvement, while the general condition remains stationary.

8.15 P.M. The King has had a quiet day. There is no change to report in His Majesty's condition. (Signed by Sir Stanley Hewett and Lord Dawson of Penn.)

SATURDAY, JAN. 5TH. 11.15 A.M.

The King has had a good night, and there is a slight improvement in His Majesty's condition.

8.30 P.M. In spite of a restless day, the King's condition remains unchanged. No bulletin will be issued until to-morrow evening. (Signed by Sir Stanley Hewett and Lord Dawson of Penn.)

SUNDAY, JAN. 6TH. 8.15 P.M.

The King has had a quiet day and there is some improvement in His Majesty's condition. (Signed by Sir Stanley Hewett and Lord Dawson of Penn.)

MONDAY, JAN. 7TH. 11.30 A.M.

The King has had a fair night and there is no change to report in His Majesty's condition.

7.45 P.M. The King has had a quiet day. There is no change to report in His Majesty's condition. The next bulletin will be issued to-morrow evening. (Signed by Sir Stanley Hewett and Lord Dawson of Penn.)

TUESDAY, JAN. 8TH. 8.15 P.M.

The King has had a quiet day. The condition of His Majesty remains unchanged. (Signed by Sir Stanley Hewett and Lord Dawson of Penn.)

BOSTON CITY HOSPITAL.—The sixty-fourth annual report of this institution, which, in addition to the main hospital, comprises a contagious diseases department, sanatorium, two relief stations, and a convalescent home, is exactly a year in arrear, the facts and statistics coming down only to Dec. 31st, 1927. The hospital, which is under the authority of the Boston City Council, spent £483,000, about £100,000 of which was recouped from ward and private room patients. In-patients cost 17*s*. 3*d*. per day, and the cost of out-patients was 2*s*. 11*d*. per visit. The report contains several illustrations of the new nurses' home, one of which shows the nurses' "sitting-room" as a stately pillared hall, its polished floor strewn with rugs. The nurses have a large swimming bath and a dining-room with separate tables, each seating four. Almost all the out-patient department clinics have been reorganised on an appointment basis, which is found to be well suited to the needs both of patients and doctors.

An Address

ON

MYOFIBROSITIS AS A SIMULATOR OF OTHER MALADIES.

Delivered before the Newcastle-on-Tyne and Northern Counties Medical Society

BY GEORGE R. MURRAY, M.D. CAMB., D.C.L. DURH., F.R.C.P. LOND.,

EMERITUS PROFESSOR OF MEDICINE IN THE VICTORIA UNIVERSITY OF MANCHESTER; CONSULTING PHYSICIAN TO THE ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE, AND TO THE MANCHESTER ROYAL INFIRMARY.

THE muscles make up about 40 per cent. of the weight of the body and actually weigh rather more than all the other organs together, including skin, fat, and blood. They are subject to all the stresses and strains of daily life, which vary greatly with the occupation followed. They are also apt to be affected, directly or indirectly, by the many changes in temperature and humidity which are characteristic of our British climate, in a manner we do not fully understand. Under these circumstances it is not surprising that the voluntary muscles are liable to suffer. Very little attention is paid by medical and surgical teachers to the varied symptoms which may be caused by diseases of the muscles compared with that devoted by the anatomist to their structure and distribution. Little space is devoted to this subject in the standard text-books of medicine. In one I pages out of 943 deal with the muscles. Ten ages are concerned with rare muscular diseases and nly one with fibrositis, the commonest of all. In nother text-book three pages out of 1711, and in nother two pages out of 1139 deal with fibrositis. Naturally students regard muscular diseases as of ttle importance and in after life are apt to ignore hem when searching for the cause of a pain. I hope o be able to show that this attitude of mind is apt o lead to unnecessary errors in diagnosis, and also o show how they may be avoided.

Myofibrositis has various names, such as myalgia, heumatic myositis, muscular rheumatism, or simply brositis, and this diversity of nomenclature is apt to ause confusion in the mind of the patient and loss of onfidence when he is told by one medical man that e has myalgia and by another that he suffers from brositis, so it is well to explain that these various erms really signify the same condition of inflammation f the fibrous portion of a muscle. This subject is of uch practical importance, as fibrositis, in the form f either myofibrositis or neurofibrositis, is one of the ommonest causes of pain in this country and is esponsible for a great deal of pain and disability. ir Walter Kinnear has shown what a loss to the nation s caused by the prevalence of industrial rheumatism, nd has estimated that in 1927 not less than 5,000,000 was paid under the National Health nsurance Scheme in Great Britain on account of heumatism, and that some £12,000,000 was lost in ages from the same cause. We may conclude that large proportion of this disability is really due to brositis. In addition to this fibrositis is apt to masquerade as a more serious malady and so give rise o much unnecessary anxiety if its true nature is not romptly recognised. Severe pain cannot be ignored, o medical advice is usually sought at an early stage. light and intermittent pain is often borne for long ithout complaint, though in time it is apt to give se to morbid fears. When relief is at last requested he prompt recognition of the fact that the pain is ue to fibrositis may save unnecessary worry in those ho have begun to dread that it indicates some serious rganic disease. The immense relief shown by an nxious sufferer when he is once convinced that his ain is due to a simple and removable cause and not to a progressive and incurable malady is remarkable. There is a grain of truth in the proverb "Fear kills more than disease," and, of course, another version, "Fear kills more than the physician" is certainly true. These are the cases in which the quack is apt to find his opportunity, as, trading on the fears of his client, he may employ some drastic form of local counter-irritation such as the application of the "life-awakener," followed by rubbing in croton oil, which may effectually remove the pain. He then claims to have cured the serious malady which only existed in the imagination of his credulous patient.

It is worth considering for a moment why it is that normally insensitive muscles may become the source of severe pain. The sensory nerves are connected with the muscle spindles which lie in the fibrous tissue which surrounds the muscular fibres. The tendons are also supplied with special sensory nerve-endings. In health we are not conscious of the impulses received from these structures. When, however, the muscles are strongly compressed, as in tetanus or in ordinary cramp, we at once become unpleasantly aware of their existence. In fibrositis these nerve-endings are irritated by the inflammatory exudate and there is a constant aching pain, which is aggravated by any contraction which compresses them and excites them still more.

DIFFERENTIAL DIAGNOSIS OF PRÆCORDIAL PAIN.

Pain which is felt in the præcordial region may be a source of anxiety to both patient and medical man; to the patient because he associates pain in this area with disease of the heart, and to the medical man because he realises that such a pain may be due to some form of angina pectoris. Fortunately, on investigation the pain often proves to be due to a local myofibrositis. It is important to be able to recognise this with certainty. I am not referring to pain in this area occurring in the course of an acute illness, such as pleurisy or pericarditis, which may be recognised by definite physical signs, but to pain in those who have no fever and are able to go about. Examination of the cardiovascular system reveals no abnormal physical signs, but this negative evidence does not eliminate the possibility of the pain being due to angina pectoris. In true angina the pain is intermittent and is brought on by exertion, emotion, or sudden chilling of the surface of the body. It tends to radiate across the chest and may extend into one or both arms or up the side of the neck—a distribution which may be simulated by fibrositis. The pain of fibrositis is induced or aggravated by use of the affected muscle, usually the pectoral or intercostal muscles, but not by other forms of exertion, such as walking uphill. It is unaffected by emotion. It is not accompanied by a sense of constriction or by the sudden fear of impending death which is so characteristic of some attacks of angina. Although rest eases both kinds of pain the well-known immediate relief afforded by the use of vasodilators in angina is not experienced when the pain is due to fibrositis.

Helpful as careful attention to these points may be, more positive evidence of the presence of fibrositis must be looked for. Careful palpation of the pectoral muscles in the relaxed condition with the arms hanging by the side may reveal the presence of a tender swelling near the lower border. The muscles should then be brought into action by asking the patient to press the palms of the hands firmly together with the arms extended in front of the chest. Firm pressure over the sternocostal insertions of the muscle will often elicit marked tenderness. On palpation of the rest of the muscle local swelling may be defined and its tenderness appreciated. The condition of the intercostal muscles may also be examined in the same area by making pressure over each space while deep breaths are drawn. The following two cases illustrate these points:—

A medical man brought his wife to see me because she was anxious about a pain situated at a point just above the left breast. This pain at times extended up the left side of the neck and was also felt in the left arm. She also suffered

from the hot flushes incidental to her age, which was 48. This lady had been in the habit of studying her husband's books and, as a result of her medical reading, she had come to the conclusion that she was suffering from angina pectoris. She had nervous tachycardia, but otherwise the cardio-vascular system was normal. On further inquiry it was found that the pain first came on after unusual efforts had been made with the arms and shoulders, was not induced by walking exercise, and was not paroxysmal in character. Examination showed that there was fibrositis of the left pectoral muscle at the point where the pain started and also at its sternal attachment. There was also fibrositis of portions of the left sternomastoid and deltoid muscles which accounted for the extension of the pain to the neck and arm. It is easy to understand how a woman at the climacteric, when morbid fears of disease are common, with a little medical knowledge, which is proverbially dangerous, became convinced she was suffering from angina pectoris. It is not unlikely that some of the cases which have been described as false or vasomotor angina have been due to fibrositis.

Another case was that of a man aged 28, a "tackler," who had suffered intermittently for four years from a pain in the left side of the chest. Shortly before the pain was first felt the muscles of his shoulder, arm, and chest had been subjected for a time to unusual strain. Since then he had been liable to severe attacks of pain commencing at a point just above the left nipple. He was free from pain on waking, but any exertion after rising, such as stooping to lace his shoes, might bring it on. On some days the pain did not come on until the afternoon, but it occurred at some time or other every working day. The pain at times had extended round to the axilla or up the left side of the neck as far as the ear, and at one time it used to reach the middle of the upper arm. Occasionally he had palpitation, and he had been told that he had strained his heart. Such a history and the position and distribution of the pain suggested that it was due to angina pectoris. Examination of the circulatory system revealed no abnormality. The age and occupation of the patient, and the incidence of the pain after work with the arms but not after walking, all indicated that the voluntary muscles and not the heart were at fault. On careful palpation a tender swelling was found near the lower border of the pectoralis at the point where the pain usually started. This swelling was felt most distinctly when the arm was held up above the head.

Fibrositis of the pectoral muscles appears to be more common on the left side than on the right. This is remarkable, as the right arm is used more than the left. Possibly this difference is more apparent than real, because a pain which is felt on the left side in the præcordial region is more likely to give rise to alarm and a desire for advice and treatment than a pain on the right side.

Quite recently, however, I have seen a case in which fibrositis of the right pectoral muscle had caused in the mind of the patient grave fears that he was suffering from cancer of the right lung. His own medical man, even when a radiogram of the chest had shown a normal appearance, had not convinced him that his fears were groundless, and so he sent him to me to endeavour to disabuse him of this obsession, which had originated after the death of a friend from malignant disease of the lung.

The Importance of Rest in Treatment.

While considering fibrositis in this region we may recall the principles laid down by Hilton in his well-known "Lectures on Rest and Pain," and emphasise the importance of securing adequate rest and relaxation of these muscles in the treatment of this condition. Dr. R. T. Williamson has drawn attention to the importance of support and fixation of the arm in the treatment of brachial neuritis, which is a common form of neurofibrositis. He pointed out that treatment often failed to relieve pain until the arm was fixed in a sling which supported it and raised the elbow sufficiently to elevate the clavicle and prevent the weight of the arm from dragging on the shoulder and nerves. The value of this I can confirm, and may add that the same kind of support is just as important in the treatment of fibrositis of the pectoral and other muscles concerned in the movements of the shoulder. An ordinary sling may be used, provided it is properly applied, though the double objects of fixation and elevation, so as to take the weight of the arm off the shoulder, are attained better by the use of the "Euphorus" sling, which may be worn by night as well as by day until the pain has disappeared. It may be mentioned, in passing, that this form of support is useful in the treatment of that obstinate form of myofibrositis which develops in the uppermost portion of the trapezius muscle with a well-defined local swelling in that area.

Other Conditions Simulated by Fibrositis.

Pleurisy may be simulated by fibrositis of the intercostal and other respiratory muscles, as the pain is felt in the side of the chest; it is severe and is aggravated by respiratory movements and there may be a slight temporary rise in temperature. In pleurodynia, however, there is no persistent fever, the physical signs of pleurisy are absent, and a localised area of tenderness can usually be detected in the region where the pain is felt.

Diseases of the blood-vessels may also be simulated by fibrositis. Intermittent claudication, in which, after a short walk, pain in the leg stops further progress until a brief rest has been taken, is due to inadequate supply of blood to the muscles resulting from narrowing of the lumen of the artery. In the following case the description of the symptoms as given by the patient was strongly suggestive of this condition.

A clergyman, aged 60, complained of pain in the leg at the back of the knee, which came on after he had walked a short distance and passed off when he rested. He had, in fact, an intermittent limp similar in character to the special form just mentioned. There was, however, no change in the colour of the skin and there was no sign of arterial disease. On examination the pain was found to be due to fibrositis of the hamstring tendons and was probably gouty in origin. A suitable diet was recommended, colchicum and potassium citrate were prescribed, and peat packs were applied at Buxton. He rapidly recovered and soon was able to walk about in comfort.

Occasionally a strip of the soleus muscle is inflamed and simulates phlebitis, but careful palpation shows that the tender cord-like swelling is in the muscle and not in a vein. Lumbago we all know, some of us more intimately than we like, but I do not propose to discuss the various causes of backache and how they may be distinguished from lumbago, as that is a familiar theme.

Fibrositis of the Abdominal Muscles.

Lumbago is more common in men than in women, who are more liable to fibrositis of the muscles of the anterior abdominal wall. This form often gives rise to fears of intra-abdominal disease. When you have determined that the pain is due to myofibrositis it eases the patient's mind to explain that the condition is of exactly the same character as lumbago but involves the muscles in front of the body instead of those of the back. Of all the muscles in the anterior abdominal wall the recti are the most liable to fibrositis. The pain which this causes is apt to be attributed to some serious intra-abdominal condition; it was described as "peritonitis muscularis," by J. P. Frank in 1792. In spite of the name, he evidently recognised that it affected the abdominal wall alone and not the peritoneum. The presence of three tendinous insertions in addition to the terminal attachment of the muscle explains its liability to inflammation. Pain in the right iliac region suggests appendicitis.

A man who was actively engaged in business and also hunted regularly complained of an aching pain of several weeks' duration in the right iliac region. He had come to the conclusion that he was suffering from appendicitis. There were no other symptoms. When the abdomen was examined with the muscles fully relaxed no superficial or deep tenderness or swelling could be detected. When the recti were brought into action by raising the trunk half-way between the supine and sitting positions an area of tenderness was at once found in the outer border of the right rectus just where the pain was felt. The application of iodine and belladonna ointment was soon followed by disappearance of the symptoms.

I have described elsewhere a similar case in which the pain came on after punting, soon after the patient's

ister had suffered from an attack of acute appendi-itis, so that suggestion had no doubt helped to arouse he fear of appendicitis.

Fibrositis of the upper segment of the left rectus or of its fibrous insertion into the fifth, sixth, and seventh ribs may simulate gastric disease, as it is iable to be increased after a meal if the stomach becomes distended. Otherwise it bears no relation-hip to digestion, is relieved by rest in the supine position, and is aggravated by any effort which exercises or strains the abdominal muscles. Often an actual swelling can be detected in the muscle, or at any rate an area of pain and tenderness is found when the muscle is brought into action. I have recorded a case in which pain in the right hypo-chondrium had been attributed for four years to biliary colic, but on investigation proved to be due to fibrositis of the outer part of the right rectus. A continued pain in the lower part of the abdomen may give rise to a dread of malignant disease.

The chief characteristics of fibrositis of the abdominal muscles are these. The pain is of a dull aching character, generally felt at one particular spot, from which it tends to radiate. It is relieved or removed by rest in bed at night. It comes on again soon after rising and increases in severity and in area during the day. There is no cutaneous hyperæsthesia. Certain movements may be acutely painful, especially if executed after resting in one position. For exam-nation, the patient should first of all lie flat on the back with the knees drawn up, so as to relax the muscles. On palpation a definite, slightly tender swelling may be felt in the muscles at the seat of the pain. The recti muscles should then be contracted strongly by raising the head and upper part of the trunk from the recumbent position. Firm pressure should be made with the tips of the fingers on the muscle at the point where the pain is felt, and it will be found to be acutely tender. This is the important point: the tenderness under the same pressure is far greater when the muscle is contracted than when it is relaxed. This is just the opposite to what is found when tenderness is due to some intra-abdominal disease, as the contracted muscle then acts as a defence and the tenderness is less than when pressure is made with a relaxed abdominal wall, and cutaneous hyperæsthesia is usually present. In the contracted muscle some fullness, or even a definite swelling, may be felt at the site of the fibrositis.

Headache.

The subject of headache is an important one and the determination of the cause may be difficult. Broadly speaking, headache may be due to local disease either inside, outside, or in the bones of the skull, or to changes in the nerves or the blood-vessels of the head, to abnormalities of the eye or ear, or to general toxic states resulting from maladies of the alimentary canal, kidney, or other organs; or, again, the headache may be of the paroxysmal type known as migraine. In searching for the cause of a headache it should be remembered that one cause, by no means rare, is fibrositis of the occipito-frontalis muscle and of the epicranial aponeurosis. This type of headache is sometimes called "rheumatic." In arriving at the conclusion that pain in the head is due to fibrositis the other forms of headache must be excluded by a full examination, which in these cases reveals no signs of any other malady. A fibrositic headache may simulate a cranial neuralgia, though it is generally more constant. It may be felt chiefly in the region of the occipital or frontal muscle or it may be diffused all over the region covered by the epicranial aponeurosis. Voluntary movements of the scalp are often painful, and on careful palpation small tender swellings may be detected in or at the line of attachment of the occipital or frontal muscular fibres to bone or fascia. In some cases there is a diffuse tenderness all over the scalp. The pain may be affected by changes in the weather and by exposure to cold. In men, at any rate, liability to this form of headache has not appeared to be related in any way to the amount of hair on the head. The previous or simultaneous occurrence of fibrositis of the muscles of the neck or trunk may serve as a guide to the recognition of the true nature of the headache.

An example of this type of headache is furnished by the case of a woman of 63 who complained of headache of a year's duration. None of the usual causes of headache appeared to account for it. The pain shifted from one part of the head to another and at times extended all over the top of it. It was worse when she was tired. There was a dry arthritis of both knees and an early cataract of one eye This headache was found to be due to fibrositis of the scalp.

Neuritis, which is usually a neurofibrositis, is a common cause of pain and is not infrequently asso-ciated with myofibrositis. When it occurs as an independent affection it is less liable than myo-fibrositis to cause morbid fears, because it occurs so much more frequently in the limbs than in the trunk. It is, moreover, well known that a pain referred to a particular nerve may be due to irritation or pressure at some point along the course of the nerve and not to fibrositis. Thus, in a persistent brachialgia, a search for an accessory rib is usually made with the aid of X rays; in sciatica this factor is borne in mind and a careful search is made for disease of the spine or pelvic organs. How elusive such a source of the pain may be was well illustrated by a case in which a man had a severe chronic sciatica with marked wasting of the muscles. We searched thoroughly for a local cause but failed to find one, and this was before X rays had come into general use. Later on a swelling developed in the gluteal region. On exploration this proved to be due to a hydatid cyst in the sheath of the sciatic nerve. The pain of persistent myofibrositis, like that of neuritis, is very exhausting, and its effect may be felt for some time after it has ceased. This after-effect may be experienced either when the pain is only of moderate severity but long duration, or when it is of shorter duration but greater intensity. The feeling of exhaustion is very depressing and helps to suggest all kinds of gloomy forebodings as to the source of the pain and the final outcome of the illness.

The points which may be specially emphasised are: (1) Myofibrositis is a very frequent malady not only in well-known situations, such as the lumbar muscles, but in many other muscles of whose existence we are hardly aware in health. (2) Myofibrositis must always be considered as a possible cause of an obscure pain. (3) As fibrositis is apt to cause much unnecessary anxiety, its prompt recognition is most important for the relief of the patient's mind. (4) Though not a fatal malady it causes much distress and disability and is worthy of much more attention and research than it has received hitherto.

Prevention and Cure.

We know so little about the cause of fibrositis that it is difficult to say what precautions can be taken to prevent it. Many cases date from a sudden or prolonged strain of the affected muscle to which little attention was paid at the time. This indicates that rest of an overstrained muscle until all pain has disappeared would in many cases obviate a subsequent and probably prolonged attack of fibrositis. This rest is even more important if there is any indication that some of the muscular fibres have been ruptured by a sudden strain. Those who have once suffered from fibrositis are liable to have recurrences unless they are able to determine the exciting cause in their particular case and to avoid it in the future. Any form of severe exercise which has not been undertaken for some time, such as that entailed by gardening, rowing, or salmon-fishing, and which leaves only stiffness in many men, may induce a sharp attack in those who are liable to fibrositis. This may be pre-vented by taking the exercise in gradually increasing amount at the beginning of a holiday—unfortunately a counsel of perfection for those who can only take an occasional day off from an otherwise sedentary

existence for the special form of exercise they prefer. Any chilling after exercise in damp clothes may bring on an attack, but this can usually be avoided by a little forethought. If exposure to any of these conditions is unavoidable, the ill-effects may often be warded off by a hot bath, drinks of some hot fluid to which the addition of alcohol is by no means necessary, and rest in bed. Prof. Stockman considers that fibrositis is usually the result of a secondary infection, and Rosenow has shown that myofibrositis may be caused by streptococci of low virulence lodged in the capillaries near the tendinous insertions of the affected muscles. It is therefore important to search for a septic focus in the mouth, nose, throat or elsewhere which, by causing secondary infection, subinfection, or toxæmia, may be the primary cause of the condition. If such a source is found it must be treated at once. A friend and colleague used to suffer greatly from lumbago until it was discovered that he had a marked focus of dental sepsis. As soon as this had been removed the lumbago disappeared and has not recurred. In many cases no septic focus can be found, so that other causes must play their part. A sudden onset without fever suggests the rapid deposition of some chemical irritant such as occurs in gout, and it is probable that some forms are really gouty in origin. It is important to avoid all excess of either red meat or sweets unless plenty of outdoor exercise is being taken. Certain wines, such as claret, may predispose to an attack.

At the onset of an acute attack a vapour bath at 120° F. for 15 minutes, or a hot bath with the water as hot as it comfortably can be borne, followed by rest in bed, will give much relief. At the same time grs. 5 each of aspirin and Dover's powder may be given and repeated several times at intervals of four hours. The application of a belladonna fomentation over the affected muscle will also help to ease the pain. Other useful local applications, such as a liniment composed of equal parts of camphor, menthol, and chloral hydrate, or one of the liniments or ointments containing menthol and methyl salicylate, are well known and efficient in both acute and chronic forms of the malady. In gouty cases colchicum and alkalies are of service. In subacute and chronic cases iodine is useful internally, and iodine and belladonna ointment is a valuable local application. Five grains each of guaiacum and sulphur thrice daily after food may be given in milk or in a cachet. Tincture of cimicifuga, which should be prescribed with a few minims of liquor potassiæ to prevent precipitation, is often beneficial. In prolonged or recurrent cases a course of treatment at Buxton, Harrogate, or Bath is strongly to be recommended. There is a great field of useful work for clinics specially equipped for the treatment of rheumatism, like that organised by the British Red Cross Society in London, where the benefits of hydrology and physical treatment will be available for those who could not otherwise obtain them.

Each of the forms of fibrositis mentioned may require adaptation of these general modes of treatment to suit the special requirements of the case, as, for example, in securing adequate rest for the affected muscle. In the treatment of abdominal fibrositis rest in bed is most important, but many patients prefer to put up with the pain rather than to submit to this treatment as soon as they realise that there is no internal lesion, such as a gastric ulcer. It happens occasionally that one of these cases is admitted to a hospital ward, and then the good effect of rest in bed is striking when compared with the slow progress made when treatment is carried on while the patient is up and about. The sacrifice of a little time for adequate rest in bed would be well worth while in many cases where this precaution is neglected and a chronic fibrositis becomes established. In the treatment of fibrositis of the scalp the local application of one of the remedies already mentioned may do much to relieve this form of headache.

SEGMENTAL HYPERALGESIA ASSOCIATED WITH HÆMOPTYSIS.

By A. I. G. McLAUGHLIN, M.B., Ch.M. Syd.,
ASSISTANT MEDICAL OFFICER, TUBERCULOSIS DEPARTMENT, ST. THOMAS'S HOSPITAL.

During an investigation, extending over four years, of pain and its attendant phenomena in pulmonary disease, I have observed that segmental or referred cutaneous hyperalgesia in most of my cases has been associated with recent hæmoptysis. Some of them have exhibited other reflex signs such as muscular tenderness over one side of the chest, localised tonic spasm and tenderness or, in the later stages, localised wasting of certain groups of muscles such as the trapezius, pectorals, and scalenes. When acute and subacute pleurisy has been present direct cutaneous hyperalgesia and deep tenderness respectively were found, a fact to which I referred in a previous communication.[1] Some cases presented complex signs very difficult to interpret, but in others the phenomena were so clear-cut and constant that I have thought it worth while to report examples, and to confine my remarks mainly to the association of segmental hyperalgesia with hæmoptysis.

These examples are taken from a series of over 300 cases, of which 180 gave a history of hæmoptysis. Segmental hyperalgesia was present in 42 of them. In general, the areas of hyperalgesia were discovered after the onset of the hæmoptysis and persisted for about 14 days. Sometimes the patient said that the skin had been tender for several days before the hæmorrhage. When a further hæmoptysis occurred, the hyperalgesic areas reappeared in the same position and lasted again for 14 days. The hyperalgesia was assumed to be segmental if two areas were found, one on the anterior aspect of the chest and the other posteriorly (see Figs. 1, 2, and 4), and both corresponding to part of the cutaneous distribution of the same spinal segment or segments. Each hyperalgesic area was roughly circular in shape, with a sharply defined border, about 2 inches in diameter, and they were found generally either near the apex or near the base of the chest. The apical areas (see Figs. 1 and 4) were situated close to the mid-line near the sternum in front, and near the spinal column posteriorly, but both being either to the right or left of the mid-line. The basal areas (see Fig. 2), both anterior and posterior, were found about 2 to 3 inches from the mid-line. Where a pulmonary lesion was discovered, the hyperalgesic areas were invariably on the same side as the lesion. Generally the areas were found to persist for 14 days after the hæmoptysis, and each area gradually diminished in size. It was noticed that the anterior area persisted for several days longer than the posterior. The following cases are cited as good examples of the condition.

Illustrative Cases.

Case 1. *Inextensive, inactive pulmonary tuberculosis in the right upper lobe.*—A married woman, aged 27, was seen first on April 30th, 1926, when she complained of a cough accompanied by small hæmoptyses for three days, scanty expectoration, and dull pains in the front and back of the chest. There were no night sweats, no dyspnœa, and no loss of weight. Inquiry into the family history revealed nothing relevant. The only previous illness which she could remember was a severe cough five years ago, which lasted for two months. Since then she had been entirely free from symptoms until the time of examination.

She was a moderately well-nourished woman and the weight was 8 st. 3 lb. The temperature was 98·4° F., pulse-rate 80, and respiration-rate 24. Slight cyanosis of the finger-nails with central pale areas was observed. All systems except the pulmonary were found to be normal.

The chest on inspection showed slight flattening and diminution of movement at the right apex. Palpation confirmed the diminution of movement. No appreciable alteration was detected in the vocal fremitus. The percussion note was of slightly higher pitch—i.e., impaired—at the right apex, both anteriorly and posteriorly. On

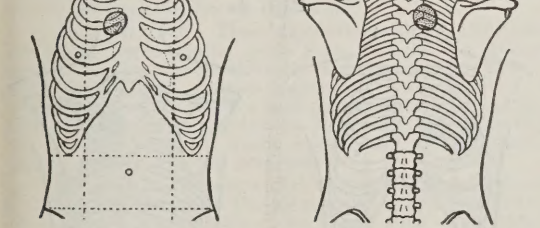
auscultation the breath sounds were heard to be somewhat distant and the expiration a little more prolonged than normal at the right apex. No adventitious sounds were heard. Two *hyperalgesic areas*, one in front and the other posteriorly, were found, each 1½ inches in diameter (Fig. 1). The anterior area was situated over the third interspace close to the sternum, but to the right of the mid-line, and the area at the back was over the fourth rib (or opposite the fourth and fifth dorsal vertebræ), immediately to the right of the spinal column. These areas correspond to part of the cutaneous distribution of the third and fourth dorsal segments of the cord.

No tubercle bacilli were found in the sputum. A radiogram taken on April 30th (the day of the first examination) showed some calcified nodes near the right hilum and a few small opacities in the centre of the right upper lobe.

Three days later the areas of hyperalgesia were still present, and were unaltered in size or position. No further hæmoptysis had occurred. Ten days after the first attendance a small area of hyperalgesia was present in front, but the area at the back had disappeared. Seventeen days after the first attendance she felt very well. She had no cough, only slight expectoration, and no pains in the chest. No areas of hyperalgesia were found.

This case showed segmental hyperalgesia involving the peripheral cutaneous distribution of the third and fourth dorsal segments in inextensive and probably inactive pulmonary tuberculosis of the right upper lobe. The hyperalgesia was situated on the same side of the lesion and lasted for about 14 days after the onset of the hæmoptysis. The calcified nodes near the right hilum with the history of a severe cough five years previously indicate probably that she then had a mild tuberculous lesion about the right hilum which healed by calcification. The hæmoptysis might have been due to the calcified nodes acting as foreign bodies and irritating the bronchial mucous membrane, or alternatively to a fresh and limited extension of the disease of low-grade activity into the right upper lobe. The subsequent history has shown that the lesion is still quiescent and has probably healed without active treatment. In the absence of tubercle bacilli from the sputum, no absolute proof existed, of course, that the pulmonary lesion was tuberculous, but the definite

FIG. 1.



Areas of cutaneous hyperalgesia in Case 1.

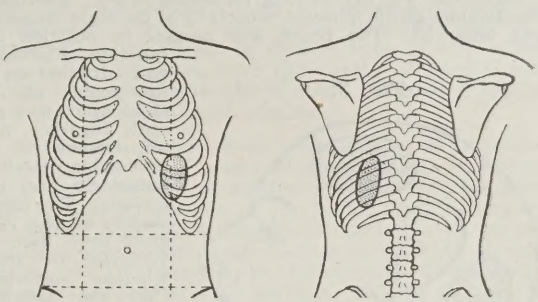
physical and radiological signs taken in conjunction with the segmental hyperalgesia were strongly suggestive that the bleeding originated in a focus in the right lung.

CASE 2. *Simple basal fibrosis with bronchial dilatation.*—A married woman, aged 30, attended St. Thomas's Hospital on April 30th, 1926, and complained of having coughed up a little blood seven days previously, and of pains in the back and front of the left base of the chest. She also complained of having had a cough for one month, with expectoration, some shortness of breath, and slight loss of weight. Her only previous illnesses were a winter cough (bronchitis) for eight years, and measles at 10 years of age. She had had five uneventful confinements. Nothing of note could be gleaned from the family history.

She looked pale and a little wasted. The temperature was 98° F., pulse-rate 76, and the respiration-rate 24. She weighed 8 st. 12 lb. The fingers were not clubbed.

The heart was found displaced 1 inch to the left. The heart sounds, however, were normal and regular, with the exception that the pulmonary second sound was slightly accentuated. The movement of the left side of the chest was diminished, especially at the base, and the percussion note was impaired over the left lung field, but more markedly at the base. On auscultation bronchial breathing was heard at the left base with a few medium crepitations, both inspiratory and expiratory. The vocal resonance and the whispered sounds were accentuated in the same region. Two areas of cutaneous hyperalgesia about 3 inches in diameter were observed, one in front situated over the fifth, sixth, and seventh ribs, and the other posteriorly opposite the eighth, ninth, and tenth dorsal spines (Fig. 2), both areas corresponding to part of the cutaneous distribution of the fifth, sixth, and seventh dorsal segments.

FIG. 2.



Areas of cutaneous hyperalgesia in Case 2.

Each area was 2½ inches from the mid-line of the body. The sputum did not contain tubercle bacilli. A radiogram of the chest showed the heart displaced to the left, and a fairly dense opacity at the left base, confirming the clinical diagnosis of left basal fibrosis.

The patient was seen again on May 3rd (three days later), when the hyperalgesic areas were found to be still present in the same positions, but were a little smaller in extent. She attended again on May 10th, one week later, when she said that she felt much better and that the pain in the back had gone. No further hæmoptysis had occurred. The anterior hyperalgesic area was still present, but was only ½ inch in diameter. The posterior area had disappeared. On May 17th she was seen again, when she said that she had no pains in the chest, no cough, and only a little sputum. No areas of hyperalgesia could be found. The physical signs of left basal fibrosis were still present.

An interesting feature in this case was that the bleeding took place from a cavity due to bronchial dilatation. Head [2] pointed out that in the excavation type of phthisis segmental hyperalgesia did not occur because in all probability in the destruction and excavation of pulmonary tissue the nerve-endings are also destroyed. Consequently, the primary component of the reflex arc is abolished, and afferent impulses can no longer pass to the spinal cord. In my series none of the cases in which the bleeding arose from a tuberculous cavity developed segmental hyperalgesia. But when, as in the above case, the source of the hæmorrhage was in a bronchiectatic cavity or bronchial dilatation, the occurrence of segmental hyperalgesia was fairly common. The explanation appears to be simple. A bronchiectatic cavity is caused by dilatation of a bronchus with no loss of pulmonary tissue, and the nerve-endings remain intact, allowing afferent impulses to pass to the spinal cord and set up cutaneous hyperalgesia.

The position of each hyperalgesic area in this case was 2½ inches from the mid-line, and in the situation of part of the cutaneous distribution of the fifth sixth, and seventh dorsal segments. These features were constantly observed in the other cases where the bleeding took place from bronchial dilatations in the lower lobe of the lung.

CASE 3. *Fibroid tuberculosis involving the extreme apex of the right lung, and also the apical pleura.*—A valet, aged 41, attended St. Thomas's Hospital first on March 10th, 1927, complaining of hæmoptysis which had commenced 28 days previously and had continued for 14 days—i.e., the bleeding ceased 14 days before the patient was first seen. He also

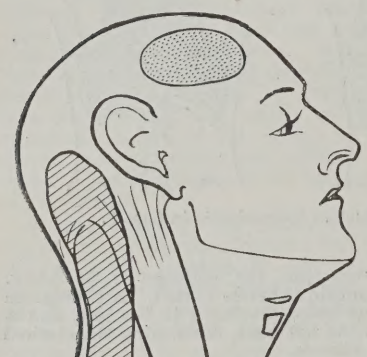
complained of pain and tenderness of the right side of the scalp and neck, commencing with the onset of the hæmoptysis. The pain and tenderness had persisted since, with a subsequent diminution of the scalp pain and tenderness, while that involving the side of the neck had increased. Other symptoms included cough, which he had had for one year, slight expectoration, night sweats, shortness of breath, palpitation, and some loss of weight.

His father and grandmother had both died from pulmonary tuberculosis. At 14 he had an attack of rheumatic fever. In 1921 and 1923 he had attacks of "pleurisy and pneumonia."

His general condition was moderately good, although it was obvious that he had lost a little weight. The temperature was 98·2° F., the pulse-rate 80, and the respiration-rate 26. The weight was 9 st. 11 lb.

The chest was of the long phthinoid type. Wasting of the shoulder girdle muscles, especially of the right trapezius, was observed. The heart was normal in position and function. Flattening and diminution of movement at the right apex was present, together with impairment of the percussion note both anteriorly and posteriorly. The breath sounds at the right apex were bronchovesicular in front, whereas posteriorly they were definitely bronchial* in character. The vocal resonance was increased over this area. A few consonating crepitations were heard at the right apex posteriorly. Over the rest of the lungs the physical signs were normal. An area of cutaneous hyperalgesia was present on the right side of the neck (as shown in the diagram (Fig. 3)), involving part of the skin distribution of the third and fourth cervical segments. The patient stated that at the onset of the hæmoptysis the right side of the forehead and top of the scalp was distinctly tender, but that this tenderness had disappeared at the time of the examination. The sputum examination failed to reveal tubercle bacilli, but X ray examination showed that a small area of old tuberculous disease involved the extreme right apex. No cavitation was visible.

FIG. 3.



The stippled area on the scalp represents the position and comparative extent of hyperalgesia said by the patient to be present at the onset of hæmoptysis. The lower area (shaded) shows the position of the cutaneous hyperalgesia found on examination.

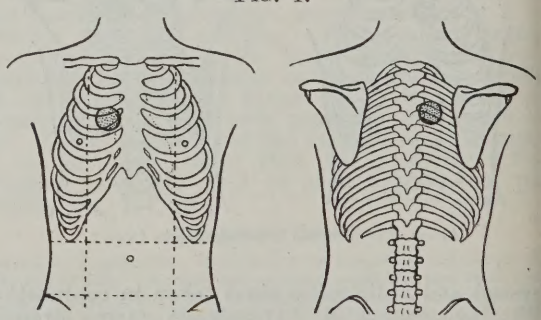
As the patient did not attend again, owing to his having left London shortly after the first attendance, I was unable to trace the subsequent progress.

There is very little doubt that the cause of the hæmoptysis was a fibroid patch of pulmonary tuberculosis at the extreme right apex involving the apical pleura, and that the hyperalgesia of the scalp and neck was associated with the onset of the hæmorrhage. This is the only case of pulmonary disease in which I have found hyperalgesia of the scalp and neck, apart from involvement of the third and fourth cervical areas in cases of diaphragmatic pleurisy. Head [2] and Carmalt-Jones [3] record cases of pulmonary disease in which referred hyperalgesia has affected the cervical segments of the cord, and Head emphasises the frequency with which hyperalgesia of the scalp and shoulder occurs in association with disease of the upper lobes of the lungs. He maintains that the afferent impulses pass by means of the vagus and are referred to the area of cutaneous distribution of the fifth cranial nerve and to the third and fourth cervical segments. It is difficult to understand why affections of the upper lobes only should set up vagal irritation. The vagus, as far as anatomical and physiological evidence shows, is supplied to the whole of the pulmonary parenchyma, and not only to the upper lobes, and on Head's hypothesis it would be expected that irritative affections in all parts of the lung would set up vagal irritation and hyperalgesia of the scalp. A more plausible explanation seems to be that in affections of the upper lobe the phrenic nerve is affected on account of its close anatomical relationship with the apex and the medial surface of the upper lobe and the afferent impulses setting up referred hyperalgesia in the areas of C. 3 and 4 are conveyed by that nerve. It is difficult to explain the connexion between the phrenic and the trigeminal nerves, but the recent work of Stopford [4 5] on the relationship between the accessory phrenic and the nucleus of the trigeminal especially the ophthalmic division, appears to offer a reasonable explanation. An attractive hypothesis would be that hyperalgesia of the scalp is only found associated with chest affections in those instances where an accessory phrenic nerve is present. The relative frequencies at least of the two conditions coincide—i.e., they are both rare.

CASE 4. *Recurrent hæmoptysis associated with recurrent segmental hyperalgesia in fibroid tuberculosis of the right upper lobe.*—This patient has been under continuous observation since, as a girl of 20, she first attended the Tuberculosis Department at St. Thomas's Hospital on March 14th, 1923, giving a history of having coughed up a pint of blood three weeks previously, with a second smaller amount one week later. She also complained of morning cough and sputum, pains in the chest, night sweats, shortness of breath, and loss of weight. Four years previously she had tuberculosis of the left knee, which was treated by immobilisation at the Westminster Hospital. Her father had died of pulmonary tuberculosis six years previously.

No definite physical or radiological signs were found, and she was sent for observation to Victoria Park Hospital, to which she was admitted under Dr. Clive Riviere, and where as resident medical officer, I had an opportunity of observing her. During her stay at the hospital from Jan. 11th to Sept. 7th, 1924 (a period of about eight months) she had a cough, expectoration, recurrent attacks of hæmoptysis, and a variable intermittent fever, rising to 100° F. in the evening. The physical signs in the chest were indefinite with the exception that the percussion note was slightly impaired over the right upper lobe, and the breath sounds over this area were distant. No crepitations were heard. The sputum was negative for tubercle bacilli on more than 30 occasions, but on one occasion a few bacilli were found. This was thought possibly to have been an error. The complement-fixation reaction for tuberculosis was negative and numerous radiographic examinations failed to reveal any definite abnormality in the chest. All the other systems were investigated for a possible cause of the pyrexia without a positive result. For example, blood cultures were persistently sterile, the blood counts normal, and urinary examinations and cultures were negative. The nervous system was normal.

FIG. 4.



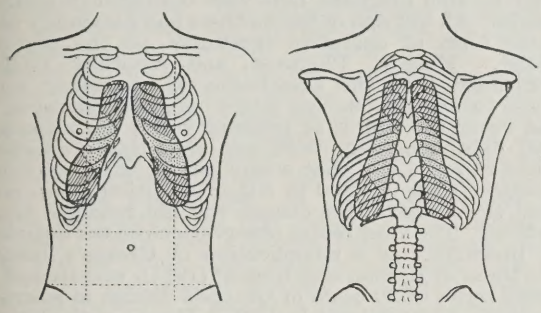
Areas of cutaneous hyperalgesia in Case 4.

* The fact that the breath sounds were bronchial in type does not necessarily mean that cavitation was present. The physical signs of cavitation differ very little from those of consolidation or thickening round a bronchus. In any case bronchial breath sounds are heard in both conditions.

During the whole of this period the patient complained of vague pains in the right side of the chest, which became worse when she had an hæmoptysis. On examination, two areas of cutaneous hyperalgesia were present, one anteriorly near the sternum, and the other posteriorly near the spinal column involving part of the areas supplied by the third and fourth dorsal segments (Fig. 4). These areas gradually became less in extent until about 14 days after the attack of hæmoptysis they disappeared, to reappear when a fresh attack of hæmoptysis occurred. The position of the hyperalgesia was constant on each occasion.

After discharge from Victoria Park Hospital she has attended the Tuberculosis Department at St. Thomas's

FIG. 5.



Areas in which segmental hyperalgesia on the chest wall was found in the present series of cases. The darker areas represent the more common situations (apical and basal).

Hospital, and I have had her under observation up to the present time. She has had many attacks of hæmoptysis at varying intervals, not obviously associated with menstruation, sometimes slight and sometimes so severe as to necessitate her admission to hospital. On each occasion the areas of hyperalgesia have been present involving the third and fourth dorsal segments. Although the patient has many times complained of headache, no hyperalgesia of the scalp or of the cutaneous distribution of the third and fourth cervical segments has been found. Radiographs and physical examination now shows a definite fibroid lesion in the right upper lobe below the apex with traction on the trachea, *but no sign of cavitation.* Tubercle bacilli are now present in the sputum. She frequently complains of dull aching pains in the right side of the chest and in the right shoulder, not made worse by coughing or breathing, but in the intervals between the attacks of hæmoptysis no areas of hyperalgesia are found. The following notes of examinations on four occasions illustrate this point.

(1) May 7th, 1926 : Three days after a slight hæmoptysis. Cutaneous hyperalgesia, each area 2 inches in diameter, present on the right anteriorly and posteriorly, involving third and fourth dorsal segments. Complains of dull aching pains in the right upper part of the chest and in the right shoulder, not aggravated by coughing or breathing. The muscles over the right upper half of the chest are slightly tender on deep pressure.

(2) June 4th : Five days after an hæmoptysis. Cutaneous hyperalgesia present in the same areas ($\frac{1}{2}$ inch in diameter). Complains of similar pain. An X ray film of the chest at this time shows some fine mottling and fibrosis below the right apex.

(3) Nov. 26th : Four days after an hæmoptysis ($\frac{1}{2}$ pint). Cutaneous hyperalgesia present in the same areas. Pain of similar nature still present.

(4) Dec. 12th : No further hæmoptysis. Still complains of pain, although less intense. Cutaneous hyperalgesia not present.

For many months, apart from the recurrent hæmoptysis, no definite clinical, bacteriological, or radiological evidence existed which proved the presence of a tuberculous focus in the lung. In the light of further observation and further experience of similar cases, the constant appearance of segmental hyperalgesia on the right side involving the third and fourth dorsal segments was an early sign pointing to the presence of an inflammatory lesion without cavitation in the right apex.

The disease is of a slowly progressive, fibrotic type, the general condition of the patient having altered very little in the past five years. The lesion in the lung has now been demonstrated clinically by the physical signs, bacteriologically by the presence of tubercle bacilli in the sputum, and radiologically by the presence of mottling in the right upper lobe and by evidence of traction on the upper mediastinum.

Hæmoptysis from a Tuberculous Cavity.—In all cases where the bleeding undoubtedly originated in a tuberculous pulmonary cavity no areas of segmental hyperalgesia were observed. The findings, therefore, coincided with Head's theory of destruction of the nerve-endings and of the consequent obliteration of the first component of the reflex arc. In a few cases, however, a single localised patch of cutaneous hyperalgesia, and sometimes with deep tenderness, was found on the anterior aspect of the chest wall directly over the cavity, and not necessarily associated with hæmoptysis. This single, localised area is an example of the direct or pleural type of hyperalgesia due to the presence over the cavity of pleural adhesions setting up a localised acute or subacute inflammation of the parietal pleura.

Congestive Hæmoptysis.—No areas of segmental hyperalgesia were found in those cases in which it could reasonably be assumed that the hæmoptysis was due to congestion of the lungs, such as in mitral stenosis † and other cardiac conditions ; in pressure on the bases of the lungs as, for example, in the later stage of pregnancy ; in pulmonary neoplasm, in chronic bronchitis and asthma, and in chronic pulmonary tuberculosis in which, according to Hebert,[6] localised congestion may occur owing to pressure on the pulmonary veins and venules by the contraction of fibrous tissue.

Discussion.

The study of this series of cases, of which the above are examples, has raised many interesting problems, such as the interpretation of the varied reflex phenomena and their paths of transmission, the innervation of the lungs and pleura, and the subjective phenomena of pulmonary disease, but it is not possible in the scope of this paper to enter into a full discussion of them. It may be stated, however, in regard to the presence of segmental hyperalgesia in association with recent hæmoptysis and in the absence of other definite clinical, radiological, and bacteriological evidence, that it may be considered an early sign of a non-excavated inflammatory lesion in the lung. Its connexion with hæmoptysis is, I think, accounted for by the fact that the latter is a very common sign of inflammatory changes in the lungs. Further, it may be stated that the situation of the hyperalgesia definitely indicates the side and site of the lesion. Apical lesions are connected with the third and fourth and occasionally the fifth dorsal segments of the spinal cord, whereas basal lesions are associated with the fifth, sixth, and seventh, and occasionally the eighth dorsal segments. The hyperalgesic areas are invariably situated, both anteriorly and posteriorly, close to the mid-line of the body, but those due to basal lesions are placed about $2\frac{1}{2}$ inches more laterally than the apical areas (Fig. 5).

The association of hæmoptysis and segmental hyperalgesia, as far as I have been able to determine from a study of the literature, has not been previously described.

† I have noticed the presence of segmental hyperalgesia in a number of cases of mitral disease, not associated with hæmoptysis, but with acute or subacute endocarditis. In these cases the hyperalgesic areas are situated on the left side close to the mid-line of the body, but midway between the apical and basal sites found in pulmonary disease.

PREGNANCY COMPLICATING SIMPLE GOITRE AND GRAVES'S DISEASE.

BY H. GARDINER-HILL, M.D. CAMB., M.R.C.P. LOND.

(From the Clinical Medical Unit, St. Thomas's Hospital.)

THE problems to be discussed in this paper are those of the incidence, results, and effects of pregnancy in simple goitre and Graves's disease. The data have been obtained from a study of the histories of 115 married women suffering from these conditions. Twenty-six were cases of simple goitre and 89 of Graves's disease. Of the latter, 71 may be classified as primary Graves's disease—i.e., patients presenting the classical picture, with diffusely enlarged vascular goitres, eye signs, tremor, tachycardia, and nervousness, in whom symptoms of intoxication had been present from the outset. The remaining 18 were cases of secondary Graves's disease in whom symptoms of intoxication had appeared after some years during which a simple goitre had been present. In these patients the eye signs were usually less prominent and the goitre smaller, harder, and more irregular than in the primary form.

Historical Review.

In the literature there appears to be little information about the incidence and results of pregnancy in patients with simple goitre, though most authorities are agreed that the effect of pregnancy on existing simple goitres is to cause a further enlargement of the gland. The step-like enlargement associated with multiple pregnancies was first described in 1875 by Lawson Tait.[1] Von Graff [2] found a marked increase in volume during pregnancy in 38·5 per cent. of goitrous women. Dock [3] also states that in goitrous areas goitres frequently increase in size during pregnancy, generally diminishing rapidly in the days immediately following.

There is considerably more information as to the incidence, results, and effects of pregnancy in Graves's disease, although there is no general agreement on these problems. Of the earlier studies, those of Seitz[4] in 1913 are valuable; he collected 112 cases of exophthalmic goitre complicated by pregnancy from his own material, from the literature, and from circular letters. His conclusions were as follows. Hyperthyroidism was not affected one way or the other in 40 per cent. of the cases, whilst in a very small number it was improved. On the other hand, 67 out of 112 cases, or 60 per cent. of the total, were made distinctly worse by gestation, and in one-fourth of these there was serious menace to health and even life. Seven patients died, five aborted, and 11 had premature labours. Three miscarriages and three macerated fœtuses were recorded. Crotti[5] (1922) came to the conclusion that the majority of cases of Graves's disease were made worse by pregnancy, and that at any rate it should be regarded as a serious complication. Bram[6] (1922), as a result of extensive clinical observations, formed the opinion that premature expulsion of the uterine contents occurred only in the minority of cases of pregnancy complicating Graves's disease, and that this depended to a great extent on the severity of the disease at the time. Mussey, Plummer, and Boothby[7] (1926) investigated the problems of pregnancy in a large number of cases of exophthalmic goitre and adenomatous goitre with hyperthyroidism. Their figures, however, appear to include only patients who were pregnant at the time of observation, and do not take into account all pregnancies after the onset of the disease. In a series of 5043 cases of exophthalmic goitre they found that only 32 were pregnant. In another series of 2185 cases of adenomatous goitre with hyperthyroidism the incidence of pregnancy was only 10. In the total 7228 cases of the two groups, only 42—i.e., 0·6 per cent.—were pregnant. These incidence figures are considerably lower than those of any other observers, and the explanation appears to be that only patients pregnant at the time of observation were included. Important information, however, is given by these workers as to the effect of these diseases on the course of pregnancy and vice versa. Most of the patients with exophthalmic goitre became pregnant during a period of remission of the disease. Twenty-three patients were delivered normally at full term and all but two of the babies were alive and normal at birth. One of the two was stillborn and the other case untraced. Two patients, on the other hand, aborted, two were delivered prematurely, two were pregnant at the time of observation, and three were untraced. Of the ten women with adenomatous goitre with hyperthyroidism who became pregnant nine were delivered of normal babies. All but one of the mothers had previously had some form of operative treatment on the thyroid gland. Mussey, Plummer, and Boothby finally concluded that the association of pregnancy with these two conditions was a rare one, but that when it did occur the course of pregnancy and the maternal and fœtal mortality were not appreciably affected. They thought also that complications were not more frequent than is usual in either condition alone, and that the course of the disease was not rendered more difficult. The most recent observations on the question of pregnancy as a complication of Graves's disease are those of Hyman and Kessel[8] (1927), who studied a small series of 20 cases of Graves's disease in married women. Nine patients had 12 children; of the latter, one was stillborn and the others normal. This they think is about the average expectancy. Pregnancy, labour, and the puerperium were normal in all. The feature which these authors especially emphasise is the amelioration of the symptoms of Graves's disease which usually occurred during pregnancy. In their cases there was seldom any relapse afterwards.

Simple Goitre.

Of the 26 cases of simple goitre to be discussed, all but two were sporadic. Twelve of these had originated primarily in adolescence and persisted into adult life, while the remaining 14 had developed in adult life. It is remarkable that in all but two of this latter group the goitre developed originally during pregnancy or the puerperium. It would seem, therefore, that simple goitre, developing in adult married women at times other than these, is comparatively rare. Full

tails of the pregnancies and their effect on the ırse of the disease in these two groups of cases have en summarised in Tables I. and II.

The incidence of pregnancy in the group of cases own in Table I. is well up to the average. Four of ese patients had one child, three had two children, o had three children, and three had four ildren each. Pregnancy was carried successfully to l term in the majority. There were three instances which the thyroid condition was perhaps responsible miscarriages. In the first, Case 4, four healthy ildren were born, and the fourth pregnancy resulted twins and was accompanied by a very marked pertrophy of the thyroid. Subsequently, symptoms hypothyroidism developed, which were not cognised or treated. This patient became pregnant 13 occasions during the next seven years, and each ne miscarried at the third or fourth month. In e second patient, Case 9, the first pregnancy resulted miscarriage. She had had a goitre since the e of 10, but a hemithyroidectomy which had been rformed just before her marriage had resulted in mptoms of hypothyroidism. As a result of treat-ent with thyroid extract, she subsequently had o successful pregnancies. In the third instance, se 12, the history was very similar to that in the st case. There was a strong family history of itre, and the family lived in a goitrous area. The tient herself developed a goitre at puberty. She arried at the age of 23 and gave birth to four healthy ildren. Six subsequent pregnancies resulted in ree stillbirths and three miscarriages. All these egnancies occurred between the ages of 23 and 32. e had not received any treatment with thyroid tract. In this case it seems probable that the yroid had become exhausted by repeated pregnancies.

The effect of pregnancy on the goitre was in the ajority of cases a further hypertrophy of the gland, d in multiparæ the steplike enlargement which was und by Lawson Tait. In both the patients on om partial thyroidectomy had been performed fore pregnancy occurred there was a recurrence of e goitre during pregnancy. As in the series of cases goitre developing in married women in adult life, ese patients also almost invariably developed mptoms of hypothyroidism in later life.

cidence, Results, and Effects of Pregnancy in Simple Goitre developing originally in Adult Life.

The details of the 14 patients in this group are ven in Table II.

The incidence of subsequent pregnancies in this oup of patients can be seen in Table II. Six of the had no subsequent pregnancy, though how far this s the result of the thyroid condition it is impossible say. It has, however, been frequently noted that yroid deficiency is often accompanied by sterility, ich can be overcome in a certain proportion of tients by treatment with thyroid extract. There no doubt that a considerable degree of thyroid ficiency was present in the majority of the cases der discussion after their first pregnancy, and from e information which could be obtained it did not pear that they had received adequate treatment th thyroid extract. The remainder, eight, of this oup of patients had had subsequent pregnancies, lf of them a single pregnancy, three two pregnancies, d one three. This is probably rather below the erage expectancy.

The development of goitre during pregnancy did t appear to have any harmful effect on pregnancy, in every patient in whom it occurred the pregnancy ring which the goitre started was successfully ried to term. In these patients also, all subsequent egnancies were successfully completed.

The effect of pregnancy on the goitre was in nearly ery case the same—i.e., a further hypertrophy of the nd. In later years the majority of these individuals veloped well-marked symptoms of hypothyroidism. here is one instance, however, Case 2 in Table III., of a goitre which was apparently unable to hypertrophy. In this patient definite symptoms of myxœdema developed after the puerperium. As a result of treatment with thyroid extract these symptoms disappeared, and two years later a further pregnancy occurred and was carried to full term with complete success.

Primary Graves's Disease.

The disease in eight of the 71 cases of primary Graves's disease originally developed during pregnancy. In six this had no adverse effect on the pregnancy, which pursued a normal course to full term. In the seventh patient, although the pregnancy was carried to full term, the child was stillborn. The eighth patient miscarried at three months, very shortly after the onset of the disease. It may be concluded, therefore, that primary Graves's disease developing during pregnancy in the majority of cases—in this instance 75 per cent.—does not materially affect the course of pregnancy.

In 40, or 56·3 per cent. of the 71, the patient was first seen within two years of the onset of the disease, during which time there had been little possibility of a subsequent pregnancy. The majority were either in hospital or under active medical supervision for the greater part of this time. These cases, therefore, can be eliminated from the discussion. Details of the remaining 31 patients (43·7 per cent.) are given in Table III. In these cases an interval of two years or more had elapsed since the onset of the disease.

From Table III. it can be seen that pregnancies occurred in 17, or 54·8 per cent., of the 31 cases in which the interval of time after the onset of the disease was sufficiently long to have made it a possibility. In spite of the fact that a relatively high

proportion of patients (54·8 per cent.) became pregnant after the onset of the disease, there are few instances of more than one pregnancy occurring—only four in this series. One of these women had three normal children, two had two miscarriages, and the other, after a stillborn child followed by a miscarriage, ultimately had a normal and successful pregnancy.

The Effect on Each Other of Graves's Disease and Pregnancy.

A summary of the results of pregnancy (also given in Table III.) in the 17 cases in which it occurred shows that out of a total of 23 pregnancies 10 were completed normally. On the other hand, there were nine miscarriages, one premature birth, and two full-term stillborn children, while one patient was pregnant at the time of observation. To put this in slightly different form, rather more than half—54·5 per cent.—of the pregnancies were unsuccessful, miscarriage and premature expulsion of the uterine contents generally occurring. The early stages of pregnancy appear to be slightly more dangerous than the later, for the majority of the miscarriages occurred in the first four months. From the present observations it does not seem possible to obtain any guide to the prognosis of pregnancy in any individual case. The result appears to depend more on the severity of the disease at the time of pregnancy than on the length of time during which the patient has suffered from it. Although five normal pregnancies occurred in patients who had suffered from the disease for a short period—three years or less—the number of unsuccessful pregnancies in these early cases was somewhat greater. Miscarriages were also more common in the patients who had suffered from the disease for a longer time. Unfortunately, no information was available as to the dates of the three normal pregnancies in relation to the onset of the disease in Case 12, so that they could not be included. Taken as a whole, however, my experience does not indicate that the length of time the patient has suffered from the disease has any relationship to the prognosis of pregnancy.

It has frequently been observed that the symptoms of Graves's disease improve during pregnancy. Hyman and Kessel,[8] for instance, found an amelioration in their series, and many did not relapse afterwards. Mussey, Plummer, and Boothby[7] though that the course of the disease was not adversel affected. The details of the effect of pregnancy on th disease in the present series, where the informatio was available, have been summarised in Table IV.

* Previously treated by X rays.
† Relapsed owing to illness of child.

In no instance were the symptoms exaggerate during pregnancy. In eight patients, 42 per cent an improvement occurred during pregnancy witho any subsequent relapse, whilst in nine patient 47 per cent., the improvement was not maintaine In two women an improvement during pregnancy wa followed by hypothyroidism. If these two cases a included with those of the first group, it can b concluded that in about half the patients the improv ment in the symptoms of the disease which occurre during pregnancy was more or less permanent, whil in the other half there was a relapse. To some exte this question of permanent improvement or relaps seems to depend on successful termination of th pregnancy. This is shown in Table IV. Unfortunatel information was only available in 19 of the 2 pregnancies. In the first column of this table, whe improvement was maintained, there is a high percentage of normal pregnancies than in the secon column, where it was not, the actual proportion normals being 62 per cent. in the first column against 33 per cent. in the second. To some exte psychological factors appear to be responsible for th relapse for, in the patients who miscarry or in who the pregnancy is not successfully terminate anxiety and disappointment at the turn of events a often advanced as the reasons for the deterioration. I others, the relapse may be due to anxiety over th subsequent illness of the child, an instance of which seen in one of the cases in the second column of th table, where the actual pregnancy was successfull completed. There can be little doubt from the figures that an exacerbation of symptoms is partic larly likely to occur after miscarriage, but is not common after a full term and successful pregnanc

A good individual instance of this is the following patie who had repeated miscarriages and ultimately a successf pregnancy. In the first place she miscarried at three month shortly after the onset of the disease, whereupon t symptoms gradually became worse. Under treatmen however, during the next six months, her condition improve About this time she again became pregnant, and duri pregnancy the symptoms of Graves's disease, including t exophthalmos and goitre, entirely disappeared. T pregnancy continued satisfactorily to full term, but the chi was stillborn. There was no return of the symptoms Graves's disease after childbirth. Four months later t patient again became pregnant and on this occasion m carried at nine weeks. As a result of this, all the symptom of Graves's disease returned, and a few months later h basal metabolic rate was found to be +59 per cen indicating a fairly severe intoxication. During the ensui year she improved under medical care and treatment, and the end of this time she again became pregnant. Again t

symptoms of Graves's disease entirely cleared up during pregnancy. At the fourth month her basal metabolic rate was normal (+5 per cent.). Pregnancy was carried successfully to full term and a normal, healthy child was born. One year after this pregnancy there had been no return of the symptoms of Graves's disease. The interesting features of this case are the improvement in the symptoms during pregnancy and their exacerbation after miscarriage, also the permanent improvement when the final pregnancy was carried successfully to full term.

The exacerbations after miscarriage could no doubt to a large extent be attributed to the mental condition of the patient, though it seems more than probable that other factors play a part in this phenomenon. It might, for instance, be suggested that when miscarriage occurs the normal involution and readjustment of glandular functions does not take place in the way that it appears to do when pregnancy is successfully completed.

An improvement in the symptoms was almost invariably noted during pregnancy. This improvement was generally maintained afterwards if the pregnancy was successfully carried to term. The most important factors in producing a satisfactory result seem to have been absence of mental stress and anxiety and adequate rest and treatment during pregnancy. When these conditions were fulfilled, the results were comparable to those of Hyman and Kessel. An amelioration in the symptoms during pregnancy was not followed by relapse afterwards. Unfortunately, in about half the cases in the present series these conditions were not attained.

Secondary Graves's Disease.

Of the 18 cases of secondary Graves's disease the primary simple goitre in 11 had persisted from adolescence, whilst in seven it had originated in adult life. The majority of the adolescent goitres first appeared about the time of puberty. In three of the adults the goitre originated during pregnancy. In a few cases there was a strong family history of goitre, but in only one instance had the patient lived in a goitrous area. The histories suggest that before the onset of thyrotoxic symptoms the goitres were in every way comparable with those already described in the section dealing with simple goitre. Before the onset of thyrotoxic symptoms the incidence of pregnancy was approximately the same as in the cases of simple goitre; pregnancies occurred in 61 per cent., whilst in the remainder, 39 per cent., there was sterility. Secondary thyrotoxic symptoms developed usually between the ages of 27 and 42; the exciting factors were shock, mental stress or sepsis, alone or in combination. There were no instances of secondary thyrotoxic symptoms developing during pregnancy or the puerperium, an observation of some interest when it is considered how frequently primary Graves's disease develops during these periods.

Pregnancy after the onset of thyrotoxic symptoms was rare in the present series. It must be pointed out, however, that in nine, or 50 per cent. of these patients, when they came under observation, the interval of time which had elapsed after the onset of thyrotoxic symptoms was insufficient to have permitted a subsequent pregnancy. The details of the pregnancies in the remaining nine cases are given in Table V.

* Both marasmic and died shortly after birth.

Pregnancies occurred in only two of these nine patients after the onset of thyrotoxic symptoms. One had two normal pregnancies and the other had one. In the former case both children were marasmic and died shortly after birth. In this patient the symptoms of the disease were very considerably exaggerated as a result of pregnancy, an indication of which was a basal metabolic rate of +81·7 per cent. shortly after parturition. In the other patient an exaggeration of the symptoms of the disease was pronounced one year after pregnancy.

Summary and Discussion.

The presence of a persistent simple adolescent goitre does not appear to affect the normal incidence of pregnancy, which in the group of cases under investigation was well up to the average. The expectancy of pregnancy in these cases was also practically normal, though there were several instances of a series of miscarriages following repeated pregnancies in patients whose thyroid condition had been untreated and in whom there were definite signs of hypothyroidism. The effect of pregnancy on the goitre in these "primarily adolescent" cases was in almost every instance the same—i.e., a further hypertrophy of the gland. In spite of this, most of these patients developed well-marked signs of hypothyroidism in later life.

The incidence of pregnancy in the group of patients who developed a simple goitre in adult life was below the average expectancy; in fact, only about 50 per cent. of them became pregnant at all. No harmful effect was noted on the pregnancy in any of these "adult" cases, though it was usually associated with a further hypertrophy of the gland, and later with well-marked symptoms of hypothyroidism.

Pregnancy as an event complicating primary Graves's disease occurred in about half the cases in which it was possible, but more than one pregnancy after the onset of the disease was comparatively rare. The results of pregnancy in these cases were poor, for there was an unsuccessful termination by miscarriage or premature birth in about 50 per cent. During pregnancy there was almost invariably an amelioration of the symptoms. In about 50 per cent. of cases this improvement was maintained afterwards.

The incidence of pregnancy in secondary Graves's disease was low, only two instances occurring out of nine cases in which it was possible. The results of pregnancy and the effects on the subsequent course of the disease were unsatisfactory, but the number of cases in this group was too few for definite conclusions.

The practical bearing of these facts appears to be as follows: A patient with a simple goitre, whether it originally develops in adolescence or in adult life, may be safely advised to entertain the prospect of pregnancy. The thyroid condition, however, should be treated by some form of thyroid extract, both during and after the event. If this is not done, although the prospects of a successful pregnancy do not appear to be decreased except in those patients who have already borne several children, a further hypertrophy of the gland is almost certain to occur, and symptoms of hypothyroidism will usually develop in later life, in a few cases fairly rapidly after pregnancy. The problem of pregnancy in Graves's disease is more complicated. The incidence figures in the present series of cases agree fairly closely with those of Seitz, but differ considerably from those of Hyman and Kessel, and Mussey, Plummer, and Boothby. These latter authors came to the conclusion that the association of pregnancy with exophthalmic goitre and adenomatous goitre with hyperthyroidism was rare (0·6 per cent.), but that when it did occur the course of pregnancy and the fœtal mortality were not appreciably affected. In the present series of primary Graves's disease the incidence of pregnancy was 50 per cent. of the possible cases. The discrepancy in

these observations is, therefore, considerable. The most probable explanation of the difference appears to be that while Mussey, Plummer, and Boothby based their calculations on the number of patients who were actually pregnant at the time of observation, in the present series of cases the details of all pregnancies, past and present, occurring after the onset of the disease, have been taken into consideration. This method appears to give more reliable incidence figures.

There is a difference also in the "results" of pregnancy in these investigations. Hyman and Kessel, and Mussey, Plummer, and Boothby found that they were well up to the average. The present results, on the other hand, agree more closely with the earlier one of Seitz. His statistics were collected from cases of his own, from the literature and from circular letters, and it is probable that they refer to a period before the extensive use of iodisation and surgical operation in the treatment of Graves's disease. This is also true of many of the present cases. It is possible, therefore, that this may account for the variation. To a large extent the poor results of pregnancy in the present series—miscarriage or premature birth in 50 per cent.—may be attributed to shocks, mental stress, and inadequate rest and treatment, for where satisfactory conditions were attained and mental stress was absent the results were generally good. The importance of taking every precaution to ensure a full term pregnancy in patients with Graves's disease cannot be overestimated. From this point of view the results in the present series are of considerable interest. In nearly every case an improvement in the symptoms of the disease was noted during pregnancy, this observation being in agreement with the findings of Hyman and Kessel, whilst the question of permanent improvement or not seemed to depend on whether the pregnancy was successfully completed or prematurely terminated. In the cases which relapsed after pregnancy there was more often than not a history of miscarriage or premature birth. On the other hand, when the pregnancy was carried to a successful termination, the improvement in the symptoms was generally maintained. It seems, therefore, that the prospect of pregnancy may be entertained by a patient suffering from primary Graves's disease if circumstances are favourable and previous treatment adequate, the degree of intoxication not too great, and cardiac and other complications absent. Under such circumstances there seems to be a good chance of pregnancy being carried to term, in which case there is an equally good chance of the disease being permanently benefited. The outlook in secondary Graves's disease, on the other hand, as judged by the few instances of pregnancy in the present series of cases, does not appear to be so satisfactory.

I wish to thank Prof. MacLean, the Director of the Medical Unit, the members of the staff of St. Thomas's Hospital, and the Medical Research Council for the facilities which enabled me to carry out this investigation.

THE "STIGMA OF PAUPERISM."—To prevent "any stigma of any kind suggesting itself to the mind of anyone making use of poor-law institutions" the Ministry of Health has sanctioned the alteration of the name of the Walsall Workhouse Infirmary to "The Manor Hospital"; the workhouse itself is to be called "Beacon Lodge." The Ministry has also approved of the appointment of a consultant physician and a consultant surgeon to avoid sending special cases to Birmingham.

LYMPHOMATA OF THE ORBIT.

BY R. E. WRIGHT, M.D. DUB.,

LIEUT.-COLONEL, INDIAN MEDICAL SERVICE; SUPERINTENDENT, GOVERNMENT OPHTHALMIC HOSPITAL, MADRAS.

THE recent article on chloroma by Ashby and Smith in THE LANCET (1928, i., 1169) stimulated me to make a survey of the records of this hospital since 1915 (inclusive) in order to pick out the various conditions of the orbit which might conveniently be called lymphomata. I had previously formed the opinion that lymphomata (lymphocytoma or lymphoblastoma) of one sort or another, although actually rare, are relatively among the commonest neoplasms of this region, if the term neoplasm include nodular collections of lymphoid tissue occurring without any relation to other definitely recognisable pathological changes. A benign localised lymphomatous aggregation (e.g., a flattened mass under the bulbar conjunctiva) is not usually regarded as a neoplasm, but my use of the term is convenient and will be clear.

Two true neoplastic conditions are outstandingly frequent in this district—namely, epithelioma arising in connexion with the lids or limbus, and retinoblastoma (glioma or neuro-epithelioma), which has usually extended to the orbit before the patient comes to hospital. The figures for epithelioma and retinoblastoma during the past eight and a half years were 35 and 23 respectively. During this period I personally examined the cases and the orbital tissues removed for diagnosis. The 23 cases tabulated below represent approximately 250,000 out-patients in 13½ years.

The *bilateral* conditions may conveniently be considered in the following groups: (*a*) as an affection involving primarily the lacrymal glands (in so far as the orbit is concerned), and (*b*) as an affection not necessarily involving the lacrymal glands, or involving them secondarily in addition to other parts of the orbit.

Lane,[1] who has made a most extensive study of the literature dealing with lacrymal gland tumours, places them in three divisions: (1) the true neoplasms (mixed tumour, carcinoma, &c.); (2) cysts; (3) symmetrical tumour-like enlargements due to Mikulicz's syndrome or lymphomata as these enlargements are often called. These are not true tumour growths, but a syndrome of unknown ætiology.

Four types of this third division are described in the literature:—

Type 1 is Mikulicz's disease or syndrome proper, in which there is a bilateral lymphomatous enlargement of the lacrymal glands, together with enlargement of one or more of the salivary glands without characteristic blood changes, usually of favourable prognosis, but capable of passing into Type 3.

Type 2.—Bilateral lymphomatous enlargement of the lacrymal glands, without salivary gland enlargement, but with lymphatic glandular enlargements elsewhere, possibly also with blood changes which have not the characteristics of a leukæmia. This is a pseudo-leukæmia, of favourable prognosis as a rule, but it may pass over into Type 3.

Type 3.—Bilateral enlargement of the lacrymal glands and possibly (but not necessarily) also of salivary glands, lymph glands, liver, and spleen, associated with a profound leukæmia either of a lymphocytic or myelocytic type, invariably fatal.

Type 4.—A bilateral lymphomatous condition of the lacrymal glands associated with hyperplasia of the gland itself, the lymphoid elements merely increasing pari passu with the epithelial elements.

The above grouping is, with minor differences, that given by Lane, who points out the much greater frequency of the conditions included under Division 3 as compared with the true neoplasms and cysts. This relative frequency is also apparent in my survey. I shall not attempt to detail the various true neoplasms that I have met with in connexion with the lacrymal gland; they are few compared with the lymphomatous conditions.

Cases recorded from this hospital prior to 1915 coming under division 3 are included in Lane's

bibliography. Since then all our cases as tabulated below are recorded,[2] except two of which the notes are now given.

CASE 1 (*Group (a), Type 1*).—Male Hindu, aged 26, was admitted on April 7th, 1928. There was proptosis of both eyes and exposure keratitis; the left cornea was ulcerated below and there was considerable conjunctival discharge. The pupils were active, but the movements of the eyeballs were restricted in all directions. The condition had lasted a month. Fundus examination showed hyperæmia and slight swelling of the right optic disc with an indistinct nasal margin. No fundus view of the left eye could be obtained owing to corneal ulceration and œdema: Right eye vision = fingers at 4 metres; left eye vision = fingers at 2 metres. The patient was very emaciated and anæmic, with coated tongue and marked pyorrhœa alveolaris. The liver was enlarged and the spleen normal. The patient was pigeon-breasted, had some dyspnœa, with wheezing respirations more frequent than normal, dullness over the right lung, slight dullness over the left base, and diminished breath sounds all over. Vocal resonance was increased on the right side.

Both lacrymal glands were enlarged as was also the right preauricular and the posterior cervical glands, as well as the parotid and submaxillary salivary glands on either side. The urine was normal. No ova of intestinal parasites were found and the Wassermann was negative. The blood count was as follows: red cells, 3,587,500 per c.mm.; white cells, 5625 per c.mm.; polymorphonuclear leucocytes, 44 per cent.; large mononuclear leucocytes, 10 per cent.; lymphocytes, 40 per cent.; eosinophils, 2 per cent.; basophils, 2 per cent.; transitional forms, 2 per cent.; hæmoglobin, 57 per cent.

Tarsorrhaphy of both eyes was done on April 7th and the patient was transferred to the General Hospital for nursing on April 14th. On May 3rd he returned with the mouth, eyes, and chest much improved. On May 5th a 12·5 mg. radium needle was inserted deep in the lacrymal gland mass on either side, parallel with the roof of the orbit. These were removed after 26 hours (325 mg. hours). A blood count on May 12th showed: red cells, 4,500,000 per c.mm.; white cells, 6250 per c.mm.; polymorphonuclear leucocytes, 50 per cent.; mononuclear leucocytes, 26 per cent.; lymphocytes, 20 per cent.; eosinophils, 4 per cent.; hæmoglobin, 70 per cent. On May 25th the orbital masses were markedly diminished; that on the right side could not be palpated, the left was just palpable. The right parotid was not so large, but the submaxillary glands were much the same. A piece of tissue removed for pathological examination on May 27th showed the Mikulicz picture considerably altered, marked fibroblastic changes having supervened. The lid adhesions were divided; the corneæ and conjunctivæ were healthy. On discharge next day: R.E.V. = 6/24 N.I.G.; L.E.V. = 6/36 N.I.G.

Radium rapidly reduced the size of the lacrymal growths. In two previous cases of this type the enlargements were reduced by X rays.

CASE 2 (*Group (a), Type 3*), *bilateral enlargement of lacrymal glands with leukæmia*, was an Indian girl of 7, who attended on May 28th, 1927, with proptosis of both eyes. The right cornea was ulcerated. It was said that the bulging had only been noticed for 20 days. A tumour mass was felt on either side between the eyeball and the orbital rim, that on the right being larger. The child had fever of a low type and was anæmic. No other glands were involved; the spleen and liver were normal. The blood showed: red cells, 4,760,000 per c.mm.; white cells, 24,375 per c.mm.; polymorphonuclear leucocytes, 24 per cent.; large lymphocytes (mononuclear), 44 per cent.; small lymphocytes, 13 per cent.; neutrophil myelocytes, 16 per cent., eosinophil myelocytes, 3 per cent.; hæmoglobin, 46·65 per cent. The Wassermann was negative. The urine contained 0·5 per cent. of albumin. A few of the monocytes contained rod-shaped bodies staining red with Leishman's stain. The patient was not treated, was discharged at request, and died.

The cases of this type had certain points in common. They were all fatal and organic arsenic did not appear to influence the condition. The blood picture varied from myelocytic to lymphocytic. The rod-shaped bodies in the monocytes were previously described[3]; blood cultures in this case, both at blood heat and in the cold incubator, were negative, and Colonel R. Knowles considered the inclusions non-organismal. Hudson does not mention them.[4]

A practical point worth noting is that in most cases either of Type I. or Type 3 exposure of the cornea is an urgent condition calling for prompt relief, for it dries and eventually ulcerates from exophthalmos and lack of lacrymal secretion. Tarsorrhaphy is a simple and efficient method of preventing loss of the eye from this cause. It gives time for treatment either by radiation or operation, and in the latter event diminishes the risk of sepsis in the dead space. As in the case described above, the lids may be opened after diminution of exophthalmos and before discharge of the patient. It seems reasonable to presume that all lymphomata not associated with leukæmia are radio-sensitive. Anyhow, X rays or radium would be well worth trying in lymphomatous conditions suspected or verified by the removal of a portion before extirpation.

Affections not Necessarily Involving the Lacrymal Glands.

There appears to be only one case in our records suitably included under Group (*b*). This was originally recorded by Colonel H. Kirkpatrick in 1916[5] as bilateral sarcoma. The neoplastic masses were at first most prominent in the lower part of the orbit. That it was not a true sarcoma was proved by the later history. In 1922 the case came under my care again and an exenteration of the left orbit was necessitated.[2] Apparently by this time the process had involved the lacrymal glands in addition to all the other structures of the orbit. There was recurrence in the socket, but it was controlled by X rays. No further development took place on this side, and on the right the condition apparently subsided altogether. Here the condition was a bilateral lymphoblastoma of a benign type, not necessarily affecting the lacrymal gland except by extension. It might be classified as: Group (*b*), Type 1, which might also include such bilateral lymphoblastomatous conditions as described by McAll.[6] I have seen two like the first case published by Bedell,[7] but bilateral. They showed lymphomatous masses under the bulbar conjunctiva, rather resembling pieces of smoked salmon, which extended backwards into the orbit over the muscle insertions.

Chloromata affecting the orbit might be placed in Group (*b*), Type 2. Those recently recorded by Ashby and Smith[8] and Cohen,[9] for example, show affinities with Group (*a*), Type 3, above. They have the common characteristics of a rapidly fatal leukæmia appearing in children. They differ in the type of orbital involvement and the colour of the new-formed tissue. The nature of the cells in the masses is chiefly myelocytic, but apparently may be lymphocytic, in which case the orbital involvement would be lymphoblastic. In chloromata there are bony foci which are not met with in Class (*a*), Type 3. I have not seen a case of chloroma in this hospital, but the literature suggests that the lacrymal gland was sometimes secondarily involved.

A third type is discrete lymphomatous invasion of all the tissues of the orbit by small isolated nodes, as described by Coats.[10] I have seen one example which has not been reported up to now and may be briefly referred to.

CASE 3.—A female Hindu, aged 40, came under my care in June, 1925, with a proptosis of the right eye of 25 mm. The left orbit had been exenterated in this hospital eight years before. On looking up the old records and examining sections of the tissues it appeared that after the exenteration no tumour had been discoverable, but there had been discrete lymph nodes throughout the whole orbit, as in Coats's case. These had been frequently related to vessels which appeared to be unduly prominent in the tissues. Blood examination had been negative and there was no record of the fundus appearances. When I saw the woman she said that the right eye had begun to bulge a year before. Vision was 6/6. There was some œdema of the disc and dilatation and humping of the vessels. The Wassermann was negative and the blood normal. There was mitral regurgitation. The thyroid was slightly enlarged. The physicians did not consider that there was Graves's disease, but there was a doubtful lesion (? tumour—not aneurysmal) of the upper mediastinum. The cornea was protected by tarsorrhaphy, and the woman took her discharge.

Unilateral Lymphoma.

The unilateral lymphomata of the orbit may similarly be considered in two groups: (*a*) an affection involving primarily the lacrymal gland, and (*b*) an affection not necessarily involving the lacrymal

gland or involving it secondarily. The lacrymal gland is one of the main sites of distribution of normal lymphoid tissue in the orbit. It may therefore be significant to remember that small isolated portions of lacrymal gland tissue may occur all round the upper fornix, in the tarsus, and even round the lower fornix, and that phylogenetically the gland mass has migrated to its present site from below temporalwards and upwards.

In Group (*a*) there are three types: (1) an enlargement of the gland of the Mikulicz type with salivary gland changes, (2) a hyperplasia of the gland with simultaneous increase of lymphoid tissue, and (3) a lymphomatous condition arising in the gland without enlargement of salivary glands or lymph glands, and without evidence of pseudo-leukæmia or leukæmia, such as the case recorded by Pfingst.[11] Of this type I had an excellent example this year. The large lymphoid mass caused marked displacement of the globe. The cornea was saved by a tarsorrhaphy and the mass reduced by partial excision and subsequent X ray treatment. Presumably such a condition may pass over into one of the bilateral types such as (*a*), 1, 2, or 3, but Pfingst's case showed no change three years after discharge from hospital.

In Group (*b*) may be included lymphomatous masses of any sort in the orbit, whether starting under the bulbar conjunctiva (e.g., the first case recorded by Bedell)[8] under the palpebral conjunctiva, or deeper in the orbit.

Bilateral.

(*a*)	(*b*)
Type 1.	One case (1916).
Five cases Mikulicz's syndrome. 1922, 1923, 1924, 1925*, 1928	
Type 2. Nil.	Nil. (Chloroma.)
Type 3.	One case (1925). Discrete lymphomatous infiltration (Coats).
Five cases leukæmia 1918, 1920, 1922, 1926, 1927	
Type 4. Three cases hyperplasia.	

* Not recorded in detail except in our laboratary records.

Unilateral.

(*a*)	(*b*)
Type 1. One case (Mikulicz) (1926).	Five cases: One each— Extending from neighbourhood of plica.
Type 2. Nil. (It is thought that an example occurred, but the notes cannot be traced).	Extending underneath the bulbar conjunctiva and backward.
Type 3.	Extending from upper lid.
Two cases .. 1922, 1928	Main mass in inferior temporal region of orbit.
	Main mass just below brow.

Two of the bilateral cases of Type 3 (*a*) showed a blood picture indistinguishable from myelogenous leukæmia. Coats[10] states that in myelogenous leukæmia local tumours are rare and do not appear to have been recorded in the orbit. In making this statement he must have considered that the leukæmia met with in bilateral lymphoblastoma of the lacrymal gland is not truly myelogenous. Inflammatory aggregations of lymphoid granulation tissue have been excluded and also localised infiltrations confined to the palpebral conjunctiva and lids. There is no doubt that other cases presenting themselves at the out-patient department might have been added to the 20 here tabulated had they been accurately written up. This may seem a very small number when one considers the approximate number of out-patients during the period which the survey covers, but although actually rare apparently these conditions come third in frequency amongst the orbital growths in this part of the world.

I have to thank the various members of the staff for their assistance, more particularly Dr. Kandaswami Pillay for his great help both in the laboratory and in the verification and assembling of records.

ESTIMATIONS OF LEAD IN TISSUES

OF LEAD-TREATED PATIENTS AND ANIMALS.*

By M. JOWETT, Ph.D.,
ASSISTANT CHEMIST, LIVERPOOL MEDICAL RESEARCH ORGANISATION;

W. J. DILLING, M.B. Aberd.,
ASSOCIATE PROFESSOR OF PHARMACOLOGY IN THE UNIVERSITY OF LIVERPOOL;

AND

W. BLAIR BELL, M.D. Lond.,
DIRECTOR, LIVERPOOL MEDICAL RESEARCH ORGANISATION
PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY IN THE UNIVERSITY.

The lead treatment of cancer has made it desirable to obtain information about the distribution of intravenously injected lead preparations among the tissues of the patient. Such information is of toxicological importance, and should be significant in determining the manner and kind of lead treatment as well as the auxiliary measures to be adopted—for example, the subsequent elimination of the lead. Little information on this subject is available. In most of the experimental work on animals discussed by Aub *et al*[1] the lead was introduced otherwise than intravenously, and the information obtained was sufficient to show that the mode of introduction of lead has a considerable influence on its distribution. N. Waterman[3] gives the results of lead estimations made on the tissues of one lead-treated cancer patient, obtained post mortem. While the tumour contained 102 parts per million of lead, the organs contained much less, the spleen showing the highest content with 55, followed by liver, bone, lung, and kidney. The drug employed was apparently similar to the electrically-prepared colloid used by us. In three cases of Rous fowl sarcoma treated by the same author with lead undecylate, although the treatment retarded the progress of the disease, the results are not quite so definitely in favour of the original tumour having the highest lead-content of any tissue. The ovary showed in one case the highest lead-content of any observed in the series. Apart from this, either the original tumour or the lung (when there were pulmonary metastases) contained the largest quantity of lead. Moreover, Waterman found that tumours treated with lead in vivo were not so readily transplanted as untreated neoplasms.

The present paper records findings concerning the lead-content of normal and neoplastic tissues after treatment with lead. These are rather fragmentary but should be of some value; so far as they go, they lend support to the view that the lead-content of malignant tissue is higher after treatment than

* This investigation was undertaken on behalf of the Liverpool Medical Research Organisation.

that of normal tissues from the same subject. Two experiments are also reported in which cats heavily treated with lead were killed a few hours later. They provide information on the immediate localisation of the lead after intravenous injection.

Analytical Method.

The wet tissues, after being weighed and roughly dried, were incinerated in an electric muffle furnace at 550–600°C. The ash was brought into solution by several extractions with hydrochloric acid. (The method followed is essentially that of Fairhall,[1] but it is thought desirable to specify some of the details, as few are given by this author.) The acid solution was then treated with caustic soda to bring the pH to a value of about 1·5 or more, as high a pH being reached as is consistent with avoiding precipitation of phosphates. Methyl violet was the indicator used. The solution, after being thoroughly bubbled with sulphuretted hydrogen, was allowed to stand overnight and then filtered through Whatman No. 40 filter paper. The precipitated lead sulphide was washed with sulphuretted hydrogen water and dissolved in hot nitric acid. The solution was neutralised with strong caustic soda and then made acid to phenolphthalein with acetic acid, a little solid sodium acetate being added to keep down the acidity. A few crystals of potassium chromate were added to the hot solution, and this was allowed to stand a few days. The precipitated lead chromate was then thoroughly washed on the filter with dilute sodium acetate solution, which serves to prevent the precipitate from passing through the filter. The lead chromate was brought into solution with dilute hydrochloric acid, and titrated at once with N/200 thiosulphate in the usual way, after adding potassium iodide. The iodine-starch colour tends to return after completion of the titration much more rapidly than when pure lead salts are being analysed; iron as an impurity may be the cause of this. The effect is variable, and is sometimes enough to make the values rather uncertain. It might perhaps be eliminated by precipitating the lead as sulphide twice.

The method used in the present work is not entirely satisfactory, as amounts of lead below 1 mg., and especially below 0·5 mg., are not accurately estimated. For a number of reasons, such methods as that involving the use of radioactive isotopes [2] or electrometric estimation of lead, which is being studied by our colleague, Dr. H. Millet, appear more promising.

Experimental Work on Lead-treated Cats.

Cats were given intravenous injections of an electrically-prepared lead colloid (about 0·5 per cent. of lead). The injections took place over a period of several hours, and the animals were killed an hour or two later. Thus there was no time for excretion of lead, and the distribution of the metal represents the state of affairs very soon after injection. Cat 1 received 365 mg. of lead and Cat 2 500 mg.; both animals weighed about 2·7 kg. The dosage was thus extremely heavy. (Tables I. and II.)

TABLE I. (Cat 1).

Tissue, &c.	Wet weight in g.	Mg. of lead.	Parts of lead per million.
Liver	80·9	149·6	1850
Lung	38·6	12·8	330
Bone (with marrow)	44·1	1·53	35
Kidney	10·6	0·98	90
Muscle	243·2	0·69	3
Blood	4·1	0·63	150
Heart	7·05	0·14	20
Large intestine (with contents)	76·7	0·0	0

TABLE II. (Cat 2).

Liver	75·8	207·1	2730
Lung	10·6	73·4	6920
Intestine and stomach	116·7	68·7	590
Blood	68·4	19·9	290
Kidney	18·7	4·1	220
Bone (with marrow)	25·5	2·65	100
Heart	6·35	1·87	290
Muscle	139·4	0·33	2
Brain	21·2	0·20	10
Urine	16	0·11	8
Intestinal contents	28·2	0·04	1

The figures evidently refer to a state of affairs when a fair amount of lead is still in circulation. The liver contains about 40 per cent. of the total lead injected. The discrepancy between the values for lung is partly accounted for by the fact that in Cat 2 the blood was largely squeezed out of the lung before circulation stopped. The liver and lung evidently take up the most lead. (Unfortunately the lead-content of the spleen was not estimated in these experiments. In later work, in conjunction with Miss Haworth, this organ was found to take up a relatively large amount). Bone, or more probably bone-marrow, is already taking up lead. Muscle takes up very little. The passage of lead into the intestine has apparently not yet begun.

Behrens [2] has made a study of the localisation of lead soon after injection of very small doses of lead chloride into young cats. As would be expected, the lung takes up a smaller proportion of the much more finely dispersed material. The liver-content preponderates, this organ taking up some 20 per cent. of the lead administered.

Lead Contents of Human Tissues.

The tissues were obtained at operations or after death from cancer patients treated with lead in Liverpool. In one case the placenta from a patient who was treated with lead for carcinoma of the rectum from the 20th to the 34th week of pregnancy, was examined after delivery. In Table III. the cases are so arranged that those which had most recently received injections come first. In estimating the value of the figures, it should be remembered that

TABLE III.

Case No.	Days since last injection.	Tissue.*	Wet weight of tissue in g.	Lead found in mg.	Lead in parts per million.

* In Cases 2 and 9 no tumour tissue was examined.

where the amount of lead found was small the figures are not considered very reliable. Table IV. gives details of the treatment which the nine patients had undergone. The length of time over which injections were given, the total amount of lead administered (as the electrically-prepared colloid S_7) and the period which had elapsed between the last injection and the operation or death after which the tissues were obtained, are the most significant factors determining the amount of lead likely to be found. (Tables III. and IV.)

TABLE IV.

Case No.	Age and sex.	Body weight in lbs.	Nature of growth.	Situation of primary.	Situation of secondaries.	Period in days during which injections were given.	Time in days since last injection.	Total of lead injected (g.).	Operation, post-mortem or delivery.
1	46 F	?	Carc.	Breast.	Liver.	91	9	0·325	Pm.

7	44 M	126	Sarc.	Thigh.	—	67	48	0·45	Op.
8	40 M	142	Sarc.	Perios.	—	189	84	0·52	Op.
9	38 F	98	Sarc.	R.-peri.	—	430	307	0·775	Pm.

R.-peri. = retroperitoneal Perios. = periosteal.
Perit. = peritoneum.

Summary.

While there are not sufficient data to make extended discussion worth while, certain features of interest may be mentioned.

In Case 1 the secondary carcinoma of the liver contained four times as much lead as the liver tissue in the neighbourhood, although this last material contained areas of growth. The primary breast carcinoma contained more lead than any normal tissue except the kidney. (The value for the fibroid seems improbably high.) In Case 8 the periosteal sarcoma contained more lead than the adjacent normal bone. Thus we have some evidence that lead is particularly attracted to malignant tissue though against these two cases must be set Case 6, where the sarcoma contains less lead than the normal tissues. It will be noticed that in this patient the liver also contained only a small quantity of lead.

For obvious reasons, tumours in which retrogression had occurred have not been analysed; consequently the clinical results cannot be correlated with the lead-content of the tumours in this investigation. The normal tissues contain variable amounts of lead, and cannot be arranged in any definite order for lead-content. It is significant that very little lead is present in the tissues of Case 9, where nine months had elapsed since lead was last injected, although the patient was supposed to have died from lead poisoning. The remaining cases had all had lead within three months. The suggestion is that very little of the lead injected is permanently stored. The bones do not appear to retain much lead, although Aub *et al* [1] regard them as the chief site of storage. The analytical method used is perhaps least satisfactory for estimating lead in bones.

Clinical and Laboratory Notes.

A CASE OF URÆMIA SIMULATING ACUTE INTESTINAL OBSTRUCTION.

BY LESLIE COLE, M.D. CAMB., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

The following case has interesting features :—

An unmarried woman, aged 53, was admitted to Addenbrooke's Hospital in March, 1928. The history was that in the previous autumn she had an attack of abdominal pain and vomiting which cleared up after a few days. For several weeks before admission she had become increasingly constipated, and for five days her bowels had not been opened at all. On the second day of complete constipation she began to vomit, and this symptom increased in severity until she could keep nothing down. As far as could be ascertained during this five days she passed no flatus. Urine was passed regularly in apparently normal amount. There was nothing in her past history to suggest renal disease.

On admission she complained of a severe headache and was vomiting every few minutes. On examination the abdomen was distended, especially in the left iliac fossa, and there was some tenderness in this region but no rigidity. The bladder was greatly enlarged and on catheterisation after micturition yielded 17 oz. of urine. There was no visible peristalsis, and nothing could be felt on rectal examination. The pulse was 100 and dehydration from excessive vomiting was severe. The urine had a specific gravity of 1018 and contained a moderate cloud of albumin but no blood, pus, or casts. During the next twelve hours the pulse-rate rose to 120 and the vomit developed a fæcal odour.

Two enemata failed to give any result, and on my assumption that there was an obstruction of the pelvic colon, Mr. V. C. Pennell performed a laparotomy. The whole of the colon was found to be distended with hard fæces, but there was no organic obstruction of any kind. The uterus was retroverted and appeared to be pressing on the neck of the bladder so as to obstruct the outflow of urine. It was therefore replaced in the anteverted position and the abdomen was closed.

The day after operation the blood-urea was estimated and found to be 258 mg. per 100 c.cm. After operation catheterisation was done every six hours and the bowels were eventually opened by means of repeated enemata combined with injections of pituitrin. The vomiting ceased in 48 hours and the patient's condition improved steadily. The necessity for catheterisation gradually became less and at the end of three weeks there was no residual urine after normal micturition, so it was discontinued. The constipation also grew less and the bowels opened regularly with the assistance of salts and aloes. The patient felt very nearly well, was eating with appetite, and getting up. The urine was of normal specific gravity, and contained only an occasional faint trace of albumin and no other abnormalities. The blood-urea was 28 mg. per 100 c.cm. The patient recovered and was well six months after discharge from hospital.

This case, apart from its diagnostic interest, well illustrates the profound effects of urinary retention on the kidney. This factor is only too well recognised by surgeons who, in cases of enlarged prostate with urinary retention, only perform the major operation after preliminary drainage of the bladder, thereby allowing time for the kidney to excrete toxins and waste products which have been dammed back in the blood.

In this instance retention was first caused by the combined effect of fæcal accumulation in the pelvis and the retroverted uterus pressing on the neck of the bladder. The toxæmia from profound constipation probably played its part by lowering the muscular efficiency of the bladder so that it could not overcome the obstruction. Once this occurred secretion by the kidney was seriously interfered with, as was shown by the uræmic state and the high blood-urea. The fact that the urine was normal but for some albumin suggests that this was a pure pressure effect and was not due to an associated nephritis. The rapid

clinical improvement and fall of blood-urea to normal during regular catheterisation was very striking.

I am indebted to Dr. E. P. H. Dudley of Caxton for the early history of this case.

A CASE OF CHRONIC MENTAL DISEASE ASSOCIATED WITH OVARIAN DYSFUNCTION.

By ALFRED DANBY, F.R.C.S. EDIN.,
HON. ASSISTANT GYNÆCOLOGICAL SURGEON, GENERAL HOSPITAL, BIRMINGHAM; VISITING GYNÆCOLOGIST, CITY MENTAL HOSPITALS;
AND
KATHLEEN SYKES, M.D. LOND., D.P.M.,
MEDICAL OFFICER, RUBERY MENTAL HOSPITAL.

WITHIN recent years a considerable amount of attention has been directed to the organic factor in the ætiology of mental disease, and in this connexion the following case seems worthy of record:—

The patient, aged 32, had been married four years and had no living children (she had had one stillbirth and a miscarriage at six months). She was admitted to a maternity hospital in June, 1921, suffering from ante-partum hæmorrhage and albuminuria. Placenta prævia was diagnosed, an internal version performed, and a 28-weeks' fœtus delivered. After delivery there was an intermittent temperature, and on the ninth day of the puerperium she became restless and confused, and as acute mania supervened she was transferred to a mental hospital. There was then evidence of puerperal infection, which subsided after a fortnight's treatment. Mentally she was described as confused, restless, and hallucinated, and at times excited. She remained like this for four years, and on Sept. 18th, 1925, she was transferred, as a case of chronic confusional insanity, to Rubery Mental Hospital, under the care of Dr. T. C. Graves, who has kindly placed these notes at our disposal. She was then in fair health, pale, and rather obese. Her facial appearance was striking: the features were coarse, resembling the acromegalic facies sometimes seen in pregnancy. Her menstrual cycle was irregular $\left(\frac{1-16}{14-63}\right)$, sometimes scanty, and at other times profuse. The Wassermann reaction of the blood and examination of the urine were negative. A gynæcological examination disclosed a lacerated and infected cervix, associated with a subinvoluted uterus. The right ovary was prolapsed, enlarged, and tender. The infection of the cervix cleared up with local treatment. Endocrine and non-specific protein therapy were tried for definite periods, and injections of collosol calcium were also given. An ear and throat examination by Mr. W. S. Adams showed that both tonsils were hypertrophic, and the right membrana tympani was retracted. He removed both tonsils by blunt dissection on Oct. 31st, 1926, and also performed a general sinus examination and drained the left antrum on April 24th, 1927. An encapsuled abscess was discovered in the right tonsil, and the antrum was found to contain muco-pus. There was a relative improvement in the mental condition after each of these operations, especially after the second, when she became less confused and quieter. It was noted, however, that during the whole of the period, and also for three or four days before and after the menstrual flow, she relapsed to her former confused faulty and restive state. She passed the summer of 1927 oscillating between two states. At times she was deeply confused, faulty, resistive, and impulsively violent, having to be nursed in a single room in strong clothing and on a straw mattress. At other times she would dress neatly, mix in a friendly way with the other patients in the general ward, and could actually be allowed out for a few hours with her husband. The change from one state to the other was in direct relation to the phases of the menstrual cycle.

On Sept. 29th, 1927, a pelvic examination under general anæsthesia showed evidence of chronic inflammatory changes of the adnexa associated with a subinvoluted uterus. A diagnostic curettage was performed at the same time; the endometrium was much thickened, and histologically there was considerable hyperplasia of the uterine glands, although it was in the intermenstrual phase. As there was no material mental or physical improvement after this operation a laparotomy was performed by one of us (A. D.) on Feb. 11th, 1928, during the usual intermenstrual remission of symptoms. The operation disclosed definite evidence of long-standing pelvic inflammation; there were many adhesions, both Fallopian tubes were thickened, the ovaries were cystic, and the uterus was subinvoluted. A right salpingo-oöphorectomy was performed; the left tube was conserved, but the cystic portion of the left ovary was resected. The abdominal wall was closed with especial care, and the wound healed by first intention. The convalescence was uneventful. There was slight menstrual loss ten days after operation, a three-day period in March, no loss in April, and a four-day period in May. The conduct became exemplary, and the mental state appeared to be absolutely unaffected by the menstrual cycle. At an interview on May 5th, 1928, the patient was quiet, pleasant, and amenable; she was well orientated, and took an intelligent interest in her surroundings. Her memory was poor for events before her last operation, but she could clearly remember everything after that. She realised that she had been ill, and stated that she now felt a new woman. She ate and slept well. Her complexion was pink and healthy, and in marked contrast with her former thick and coarse appearance. On May 10th she was discharged to the care of her husband after six years and eleven months in a mental hospital, and up to date (Jan. 11th, 1929) there has been no return of her mental symptoms.

Pathological Report.—Right ovary enlarged to one and a half times normal size. Tunica much thickened and surface lobulated and studded with numerous distended follicles of various sizes. Macroscopically a fibro-cystic type of ovary. Sections from the ovary showed the vessels very sclerosed; cystic spaces were present, some of which contained poorly developed lutein tissue of an aberrant type.

Comment.

The outstanding feature of this case was the remarkable exacerbations of mental symptoms at a particular phase of the menstrual cycle, and their complete remission after resection of the diseased part of the ovaries. The irregularity of the menstrual process in interval, duration, and amount was a clear manifestation of disordered ovarian function; the pathological findings were in accord with this. In view of the recent work on "œstrin," and the apparent physiological antagonism between the œstrus-producing hormone and that of the corpus luteum, it seems reasonable to infer that the morbid condition of the ovaries had interfered with the normal correlation of their cyclic functions. Presumably this derangement had thrown out of gear the endocrine balance which, in this instance, had caused a psycho-pathological reaction.

Although this observation must be hypothetical, the result is arresting. It is recorded in the hope that it may stimulate further investigation into this subject.

BLOOD-SUGAR ESTIMATIONS IN THE TREATMENT OF DIABETIC COMA.

By PHILIP BAYER, M.D. ABERD., M.R.C.P. LOND.,
MEDICAL REGISTRAR, QUEEN'S HOSPITAL, BIRMINGHAM;
AND
A. VICTOR NEALE, M.D. BIRM., M.R.C.P. LOND.,
RESIDENT MEDICAL OFFICER, CHILDREN'S HOSPITAL, BIRMINGHAM; ROCKEFELLER SCHOLAR, 1928.

Diabetes mellitus sometimes presents unusual features in childhood. We have observed a diabetic child who had a blood-sugar of about 40 mg. per cent. over a period of a few weeks without any adverse signs or symptoms, and we believe that this may not be very unusual in children. It may cause great difficulty in the treatment of diabetic coma as the following case illustrates.

A girl of 13 was admitted to the Queen's Hospital, Birmingham, at 9.30 P.M. on Feb. 17th, 1927, in a state of semi-coma, for diagnosis and treatment. The parents related that the girl had been perfectly well until one week before admission, when she had complained of a shivering attack and stayed in bed for three days. After she had been up again for a few hours vomiting had necessitated a return to bed. It had recurred frequently next day, and headache and great thirst with complete anorexia had supervened. During the last few weeks there had also been considerable loss in weight. There was nothing of clinical value in the family history, and no previous illnesses of any consequence.

Her condition on admission was one of drowsiness with marked air-hunger, dry skin, subnormal temperature (95° F.), a pulse-rate of 120, and a dry throat. The deep reflexes were absent and the plantar response was flexor. The fundi were normal, but ocular tension was markedly diminished.

There was a marked odour of acetone. A large distended bladder was emptied spontaneously soon after admission. There were no detectable signs of sepsis anywhere. Urine examination revealed 6 per cent. of sugar (Fehling's method),

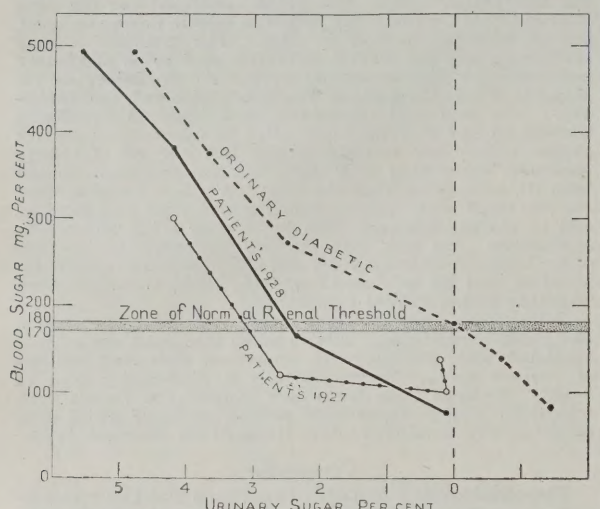

Chart to illustrate the relationship of blood-sugar to glycosuria in the patient (1927 and 1928) and in a diabetic with normal renal threshold.

a haze of albumin, and strongly positive tests for acetone and diacetic acid.

A diagnosis of diabetic coma was made and treatment was given as shown in the following table.

Table showing Treatment and Progress after Admission.

Date: Feb., 1927.	Time.	Blood-sugar mg. per cent.	Urine-sugar per cent.	Treatment.
				Period A.
17th	10.30 P.M.	—	6·0	Cal. gr. iii., sod. bicarb. gr. xv., 4-hourly. 20 units insulin.

20th	8.30 A.M.	90	—	—

Gluc. int. = glucose intravenously. Subc. = subcutaneously.

During Period A the child was treated with insulin for diabetic coma—circumstances made it impossible to do blood-sugar estimations, but sugar was present in the urine. During Period B the patient was in a state of hypoglycæmia and collapse with quick feeble pulse, flushed face, and very shallow breathing. During Period C there was disappearance of the hypoglycæmic phenomena and consciousness was regained. Period D showed a marked improvement in general condition. It is to be noted that there was a rapid fall of blood-sugar following 10 units of insulin, yet glycosuria persisted.

After recovery from coma the patient was put on a diabetic diet of over 1000 calories; she passed from 6 per cent. to 8 per cent. of sugar daily, and this was readily controlled by 5–10 units of insulin in the 24 hours.

Further Investigations.

Blood count: leucocytes, 14,000; red cells, 4,500,000; colour-index, 0·8; no abnormal features in films. Blood pressure: 100/65. The blood contained 36 mg. of urea per cent., 2 mg. of uric acid per cent., and 1·2 mg. per cent. of creatinine.

The knee- and ankle-jerks returned, but remained diminished. X ray examination of the cranial sinuses, lungs, &c., showed no abnormality.

Glucose-tolerance Test.

		mg. per cent.	
Blood	9.20 A.M.	286	Before 50 g. glucose.
	10 A.M.	400	After 50 g. glucose.
	10.40 A.M.	465	
	11.20 A.M.	385	
	12.30 P.M.	330	

		Quantity.	Sugar (g.) per cent.
Urine	8.45 A.M.	145 c.cm.	7·46
	10 A.M.	110 c.cm.	6·86
	11 A.M.	125 c.cm.	9·8
	12 noon	90 c.cm.	9·8
	1 P.M.	45 c.cm.	8·4

Investigation of Renal Threshold.

April, 1927.	Blood-sugar.	Urine-sugar.
6th	303 mg. per cent.	4·2 per cent.
11th	118 „ „	2·6 „
19th	102 „ „	Trace.
29th	154 „ „	0·14 per cent.

After another attack of coma in July, 1928, the investigation of the renal threshold on August 14th showed:—

	Blood-sugar.	Urine-sugar.
10.25 A.M.	488 mg. per cent.	5·5 per cent.
11.25 A.M.	385 „ „	4·1 „
12.30 P.M.	169 „ „	2·3 „
1.10 P.M.	75 „ „	Trace.

Her condition was then very little changed since her previous admission, and 20 to 30 units of insulin were required daily to control the sugar excretion on a diet of sufficient calorific value to maintain her general health.

Summary.

1. On admission the child's urine contained 6 per cent. of sugar. She was treated with 140 units of insulin (in 20-unit doses), and as the urine still contained 1·8 per cent. of sugar a further 10 units of insulin were given. During the period it was not possible to obtain blood-sugar estimations, but one hour after the last dose of insulin the blood-sugar was 13 mg. per cent. Clinically the child had passed from hyper- to hypo-glycæmia, but still retained the glycosuria. 2. It was manifest that the renal threshold had been completely disorganised and, for the time being, the kidneys were allowing sugar to escape despite a subnormal blood-sugar. This rendered it essential that further treatment should be controlled by frequent blood-sugar estimations. 3. After the state of coma had been overcome a great susceptibility to insulin occurred, as shown by the reduction of the blood-sugar from 283 mg. per cent. to 115 mg. per cent. with 10 units of insulin, the urinary sugar falling from 3·8 per cent. to 2·0 per cent. at the same time. This further illustrated the value of blood-sugar estimations. 4. Large doses of glucose were required to raise the blood-sugar to normal limits, apparently because of the extreme degree of renal leakage and prolonged effect of insulin. 5. Four weeks after admission the renal threshold for glucose had improved, but had not become normal. 6. A recent re-examination shows the persistence of the abnormal renal threshold.

We are indebted to Dr. J. G. Emanuel and Dr. L. G. J. Mackey for allowing us to investigate and report this case.

LONDON HOMŒOPATHIC HOSPITAL.—This institution, in Great Ormond-street, W., has just received a Charter of Incorporation. The hospital was founded in 1849, and since the present building was opened in 1895 it has more than once been enlarged.

Medical Societies.

HUNTERIAN SOCIETY.

AT a meeting of this Society, held at the Mansion House on Jan. 14th, the chair was taken by the President, Dr. ARTHUR WESTERMAN, and a Hunterian lecture on

INTRATHORACIC SURGERY

was delivered by Prof. J. H. ZAAIJER, of the University of Leyden. He described the work of himself and his colleagues since 1909 on the surgery of the œsophagus and lungs. He said he had felt that positive and negative pressure anæsthetic apparatus was essential, but that the elaborate American apparatus for this purpose was unnecessary. He described the simple apparatus used in Leyden and the device used to apply the mask to the face in any position of the patient. Positive pressure anæsthesia was necessary as a precaution in unilateral as well as in bilateral pneumothorax. It was also valuable in preventing air-embolism, as illustrated by a case of a large lymphogranuloma on the front of the neck which had an extensive venous anastomosis with the chest wall. Nitrous oxide oxygen ether anæsthesia had proved very satisfactory for these cases. Experiments on animals had convinced him that it should be possible to perform an intrathoracic resection of the œsophagus in man. A young woman with a benign stricture had consulted him, as she was really starving. Gastrostomy had been performed, but the stricture could not be penetrated and a large putrefying mass had remained in the enormously dilated œsophagus. He had therefore removed a number of ribs on the left side, isolated the œsophagus, and sutured it to the thoracic wall. Twelve days later he had opened the œsophagus, making a thoracic œsophagostomy. The patient had fed herself by means of a glass bottle and bellows concealed under her clothing. The food taken into the mouth passed through the œsophagostomy into the bottle by rubber tubing, which she closed with a pressure-screw when the bottle was full. Compression of the bellows then forced the food into another tube which led it through the gastrostomy opening into the stomach. This experience had shown that the human œsophagus could be isolated from its bed for a considerable distance without undergoing necrosis, and this opened the way to treatment of low œsophageal carcinoma. The next cancer case had been treated in three stages—gastrostomy, extensive rib resection, and removal of the tumour. The œsophagus had been sutured to the mobilised chest wall and the patient had lived for three and a half months, thus proving the technical operability of carcinoma of the cardia and lower end of the œsophagus. Other surgeons had performed the operation with cure lasting for many years. In Prof. Zaaijer's opinion it was worth while continuing efforts to treat this condition by operation. He had tried several ways, but remained convinced that his own method was the safest.

Cardiospasm.

However slight the direct results of this work might have been as yet, the indirect results had already been far reaching. The commonest form of cardiospasm occurred in patients with marked abdominal ptosis, and there was always a long abdominal portion of the œsophagus with a thin circular musculature. The dilated part, above the diaphragm, had thickened musculature. He had therefore concluded that the rest-position of the subdiaphragmatic piece of the œsophagus was closure, its function being to open at the required moment. The opening muscles were the longitudinal ones, and these would be in a bad condition for work in the ptotic œsophagus. The function of the supradiaphragmatic part of the œsophagus was to push food on; if it found the cardia closed, the result became a matter of balance; so long as the force of the upper part could overcome the resistance of the cardia there would be no symptoms. When, however, dilatation succeeded to hypertrophy "cardiospasm" developed. It was a curious fact that a thick sound could always be passed through a cardiospastic œsophagus, thus suggesting strongly that the condition was not a "spastic" one. He had had success with Heller's method of splitting the circular muscle bundles, and had found that the dilatation was reduced. Influenced, however, by his theory of the origin of the condition, he had tried treatment by rest of the œsophagus—i.e., feeding for several weeks through a tube and washing out the œsophagus with salicylic or boric acid solution. This had proved very successful.

Another variety of cardiospasm might result from an excessive amount of air in the stomach. One patient had been benefited by a gastrostomy to let out the air, and had been finally enabled to return to her work by an apparatus to suck air out through the gastrostomy, to be dispersed over her shoulder. In the Middle Ages a woman like this would certainly have failed to pass the "sinking-test" for witches, as the air in her stomach would have made her float.

Organic Strictures.

Prof. Zaaijer showed slides illustrating a number of cases of organic stricture of the œsophagus treated by the usual dilating methods. He pointed out the advantage of using a thin rubber tube threaded with a silk or cotton thread. The patient would bite through an empty tube, and the thread alone would cause a cutting sensation in his throat. One patient, a man of 49, had been treated by gastrostomy and jejunostomy for gastric ulcer 14 years before. He had later experienced difficulty in swallowing, had been diagnosed as œsophageal carcinoma, and pensioned with a gastrostomy as a hopeless case. His œsophagus had been dilated by Prof. Zaaijer in the usual way and cured completely, but unfortunately he had been unable to obtain work, as he had been officially declared "incurable." For higher stricture an antethoracic œsophagus might be made by suturing a loop of small intestine to the stomach and the skin and making a skin tube above it. One patient successfully treated in this way at Leyden 11 years ago was still taking his food normally with his fellow-servants in the hospital.

Bronchiectasis.

The treatment of bronchiectasis had been carefully worked out in the Leyden clinic and a series of well-marked stages had been defined. Lobectomy was no longer a dangerous operation, and was almost a certain cure. French operators seemed satisfied with avulsion of the phrenic nerve, but in Holland, as in England, the results had not been very good. Thoracoplasty was the second stage, but it must be done so as to interfere as little as possible with the function of the healthy parts of the organ. The methods of Sauerbruch, Brauer, and Wilms damaged the upper lobes seriously and were therefore undesirable. Extended resection of the ribs over the affected lobe was a useful procedure, but must include removal of the periosteum with the intercostal muscles. This removal also lessened the shock of the operation. For one thing it saved the shock-effects of absorbing bruised muscle tissue; secondly, if the thoracoplasty failed, the subsequent intrathoracic operation became a soft-tissue manœuvre, and so was greatly facilitated; thirdly, the removal of periosteum and muscles caused adhesion of the underlying lung. The next stage was extirpation of the lobe or slow destruction of it by Graham's method. The latter involved grave danger of air-embolism and hæmorrhage. Resection in the usual way caused shock and risk of broncho-fistula. The third stage at Leyden had therefore taken the form of intrapleural plugging of the pleura after freeing the affected lobe from its adhesions as far as possible. This gave complete and permanent cure by

compressing the diseased lobe with a minimum of danger and without complications. Even, however, if the lobe were too indurated to be compressed, the final stage of lobectomy—once so feared—was not really much more serious. When the plugs were removed the lobe was found as a more or less pedicled structure in the closed pleural cavity around it, and it could be removed by slow elastic stricture of its root. This could be done in the ward without pain or shock, the elastic tube being tightened daily until the lobe necrosed and fell off—usually in about two weeks' time. The cavity was then loosely plugged with gauze and became smaller and smaller until it closed. Prof. Zaaijer showed photographs and radiograms of a number of cases, demonstrating that the patients recovered completely, with almost normal use of the arm and normal function of the remaining lobe of the lung.

The PRESIDENT recalled the visit of the Dutch admiral who had sailed up the Thames with a broom at his masthead, and the English admiral who had retorted by fastening a whip to his. Prof. Zaaijer, he said, had brought both broom and whip, sweeping away many old notions of the dangers of intra-thoracic surgery and stimulating thought. Meetings such as this performed an international service in preserving the friendship and increasing the mutual respect of two nations.

Mr. J. E. H. ROBERTS, proposing a vote of thanks, remarked that a great deal of work on the surgery of the œsophagus had been done in the north-west corner of Europe without being heard of in this country. The knowledge that surgeons could deal with bronchiectasis was not adequately spread throughout the profession, and therefore surgeons did not see cases in the early, basal, unilateral stage, but only when the condition had become diffused.

Sir JAMES DUNDAS-GRANT, seconding the vote, said that Prof. Zaaijer's demonstration had been extraordinarily convincing, and mentioned the use of radium, to the possibilities of which surgeons must not shut their eyes.

DONATIONS AND BEQUESTS.—Mrs. Jane Parton, of Percy House, Tunbridge Wells, left £22,500 for charity, including £2000 each to the Royal Blind Pension Society, Dr. Barnardo's Homes, and the General Hospital, Maidstone; £1000 each to the Cancer Hospital, Brompton, the Royal Hospital for Incurables, Putney, and the General Hospital, Tunbridge Wells; £500 each to the Convalescent Home for Children, Hawkenbury, Tunbridge Wells, and Dr. Barnardo's Cripples' Home, Tunbridge Wells.—Dr. John Cornwell Round, of Purbrook, Sydenham, left over £15,000 upon trust for two persons and on the decease of the survivor with remainder equally between the Royal National Life-boat Institution and the Samaritan Fund of St. Thomas's Hospital.—Lady James, of Springfort, Stoke Bishop, Bristol, left £750 to Bristol General Hospital and £250 to Bristol Blind Asylum.—Sir George Sheppard Murray, of Cleveland House, St. James's-square, and Barretstown Castle, Co. Kildare, left £1000 each to the Imperial Cancer Research Fund, the National Association for the Prevention of Consumption or Other Forms of Tuberculosis, and Dr. Barnardo's Homes, as an addition to capital, and £500 to Poplar Hospital for Accidents.—Mr. Edmund Murray Dalgety, of Magdalen Yard-road, Dundee, left £2800 to such Dundee charitable institution or institutions as the trustees may select; £1000 each to the Dundee Royal Infirmary and the Royal Victoria Hospital, Dundee; and £200 to the Little Sisters of the Poor, Wellburn, Lochee.—Mr. Edwin William Goodwin, of Didsbury, Manchester, left £500 each to Manchester Royal Infirmary, Ancoats Hospital, the Boys' and Girls' Refuges and Homes, St. Dunstan's Hospital for Blind Soldiers and Sailors, Manchester and Salford, the Royal Schools for the Deaf and Dumb, Old Trafford, Manchester, the Crippled Children's Help Society, and St. Mary's Hospitals, Oxford-road, Manchester.—Mr. Frederick William Archer, of Lansdowne-place, Hove, left £1000 to the Leicester Royal Infirmary, £500 to the Leicester Guild of the Crippled, £200 each to the Leicester Infirmary for the Blind, £100 each to the Leicester Wycliffe Society for the Blind and the Leicester Children's Hospital.—Lord Glendyne has made a donation of £1000 towards the £35,000 required by the Royal Northern Hospital, Holloway, in order to obtain an anonymous gift of an equal sum.

Reviews and Notices of Books.

ARTHRITIS.

Chronic (non-tuberculous) Arthritis. By A. G. TIMBRELL FISHER, *M.C.*, F.R.C.S. Eng., late Hunterian Professor, Royal College of Surgeons of England; Surgeon to the Seamen's Hospital. London: H. K. Lewis and Co., Ltd. 1929. Pp. 232. 25*s*.

PROBABLY what is commonly known as rheumatic arthritis causes in this country as much or more suffering and disability than all other chronic diseases put together. Recognising this fact and realising that there is much still to be learnt about the physiology of joints and the pathology and ætiology of chronic arthritis, Mr. Timbrell Fisher undertook the investigations which are described in this book. Although gouty arthritis and joint diseases associated with chronic affections of the central nervous system are included, the really important subjects of this work are the two conditions which are described as rheumatoid arthritis and osteo-arthritis. The author first discusses the physiology and histology of the parts forming normal joints and then proceeds to describe a number of experiments and investigations designed to advance our knowledge of the pathology of both forms of chronic joint disease and of their treatment. Probably in this country no surgeon has had a more widespread and enduring influence on the treatment of inflamed and painful joints than John Hilton of Guy's Hospital, whose lectures on rest and pain have been accepted by several generations of students and surgeons as a true gospel. Of late years it has been realised, however, that in certain cases rest is not the best treatment for a chronic inflamed joint. As Mr. Fisher points out, complete rest and cessation of function leads to atrophy of important joint elements, an atrophy comparable to the degeneration which is one of the characteristics of disease; whereas in many cases of chronic arthritis, movement favours cure and preserves function. The difficulty is that only experienced surgeons can decide in which cases to prescribe and insist on movement and in which to order complete rest, with or without the intention of procuring healing by ankylosis.

Mr. Fisher gives due importance to orthopædic measures of various kinds, but describes also the operations of arthrotomy, cheilotomy, synovectomy, excision, and arthrodesis, including his own method of approach to and exposure of the knee-joint. Rheumatism of joints is, however, as much in the domain of medicine as of surgery, and Mr. Fisher recognises medical treatment to be of the first importance.

This book is really interesting. New facts and original observations are introduced and some known facts are brought to notice in a new light and fresh inferences are drawn from them. All who have to do with cases of chronic joint disease of so-called rheumatic origin will find it worth while to study Mr. Fisher's views.

Les Arthrites Gonococciques. By HENRI MONDOR, Professeur agregé de la Faculté de Médecine de Paris; Chirurgien des Hôpitaux. Paris: Masson et Cie. 1928. Pp. 528. Fr.70.

THE arthritic manifestations of gonorrhœa were first recognised in France by Swediaur, in Berlin by Christian Theophilus Selle, and in Great Britain by John Hunter, Sir Benjamin Brodie, and the surgeon who in this book is called "Sir Astley Copper." It is probable that gonorrhœal arthritis is nowadays more prevalent in France than with us; but whether its incidence be frequent or relatively rare, its consequences are disabling and its course prolonged. A large and serious work upon this important subject is therefore welcome. Prof. Mondor protests against the use of the term rheumatism in this disease, which he rightly describes as an infectious arthritis, in its early

stages generally acute. He writes as a surgeon and is sceptical as to the value in gonococcal arthritis of medical treatment, such as serotherapy and vaccinotherapy or palliative measures. His conclusions are founded on a vast knowledge of the pathology of the disease; many pages are devoted to discussion of pathological anatomy, and Prof. Mondor illustrates his study with coloured microphotographs and other figures of considerable interest. In the clinical section the classification is elaborate, and presents the various forms and sites of disease under 14 headings. The scale of the work may be gauged by the fact that under the general heading of "Formes segmentaires" subsections deal separately with the disease as it is manifested in each segment of the patient's frame; for example, one is concerned solely with gonorrhœal feet, such as flat-foot, pseudo-gout, bony spikes and outgrowths, and "pied-cloué." Cytology, bacteriology, blood culture, serodiagnosis, vaccinodiagnosis, and fixation reactions of the disorder are treated in sections headed Laboratory Research. Much space is devoted to descriptions of cases and discussion of methods of treatment. At the outset the original focus of the disease in the genito-urinary system must receive early and thorough treatment, including necessarily the seminal vesicles in the male and the uterus and tubes in the female. For the rest, Prof. Mondor disposes politely but firmly of the arguments of those physicians who claim to have obtained results from serum and vaccine therapy. He has found no reliable evidence to justify such claims. Of the hyperbolical praise accorded to certain other methods he says: "cet amas d'adjectifs ne saurait cacher entièrement le visage de la réalité." In fact, the number of sovereign remedies advocated in the past may be taken as an index of the ill-success of treatment in too many refractory cases. Immobilisation, compression, mobilisation, massage, puncture, hyperæmia, electrotherapy, radium, auto-serotherapy, protein treatment, sero- and vaccino-therapy have also been vaunted. The author considers that of these only vaccinotherapy with puncture as a secondary measure are of much value and that surgical intervention, especially arthrotomy with immediate suture if used very early in the course of the disease, is the method of choice. His statistics seem to us to bear out his conclusions.

This work should be studied by all those who have to treat gonorrhœal arthritis. It contains a vast amount of information on the subject and abundant evidence is offered from which the reader may draw his own conclusions. The mass of facts included makes the book bulky, but it has no redundant passages, and compression would have diminished its value. There is a bibliography of 47 pages, but no index.

CARDIAC ARRHYTHMIAS.

By IRVING R. ROTH, M.D., Assistant in Medicine, Mount Sinai Hospital. New York: Paul B. Hoeber, Inc.; London: Humphrey Milford, Oxford University Press. Pp. 210. 36*s*.

TEN years ago there was a certain novelty about the cardiac arrhythmias which rendered them extremely fashionable for examination purposes and as subjects for post-graduate lectures. Now that novelty has worn off, and the well-informed practitioner has a pretty good idea of what is meant respectively by auricular fibrillation, sinus arrhythmia, and extrasystoles. He is unlikely to need a large tome on the subject, and his less enterprising colleagues, who do not trouble their heads about such matters, will certainly not read one. We do not therefore anticipate that there can be a big demand for such a work as this, for it is quite an elementary treatise and will not appeal to the specialist. Certain people, however, cannot digest condensed matter and prefer to take their mental nourishment in bulk. This work should appeal to them, for the text is clearly written and the diagrams are good, though in some cases unnecessarily elaborate. The printing and production generally are excellent.

WILLIAM HARVEY.

Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus. By WILLIAM HARVEY, M.D. With an English Translation and Annotations by CHAUNCEY D. LEAKE, Professor of Pharmacology, University of California. London: Baillière, Tindall and Cox. 1928. With five plates. Pp. xii.+228. 16*s*.

William Harvey. By ARCHIBALD MALLOCH, M.D., M.R.C.P., Librarian, New York Academy of Medicine. New York: Paul B. Hoeber, Inc. 1929. With ten plates. Pp. xii.+103.

THE Harvey Tercentenary was celebrated on the other side of the Atlantic as well as on this, and these two volumes are some of the tangible results. Prof. Chauncey D. Leake has produced an interesting and comprehensive memorial of Harvey's work in his book, which would probably have found a wider public had it come while interest in the subject was at its height. The first part of the work consists of a facsimile reprint of the first edition of "De Motu Cordis"; this includes the leaf of errata which was omitted from the facsimile issued by the Royal College of Physicians of London. The text was so inaccurately printed that this leaf is of some importance. The second part is a new translation of the treatise, which Prof. Leake believes to be "the third attempt to render Harvey's classic into current English idiom." Actually it is the fourth, but this fact in no way detracts from the value of Prof. Leake's rendering, no attempt having been made since 1847. In that year the Sydenham Society published Robert Willis's stilted and unattractive translation, and this has held the field ever since as the standard English text. The new text is a great improvement on the old. It is a sufficiently free translation to make easy reading, without departing from Harvey's intention, and for this reason the book should be welcomed in England and America. Prof. Leake has added numerous useful and interesting annotations in footnotes. His illustrations increase the value of the book, though his reproduction of Harvey's diagrams of the venous circulation in the forearm is hardly adequate.

Dr. Archibald Malloch's smaller book, based on a tercentenary address delivered in Boston, provides an admirable companion volume to the new translation. In small compass he includes a study of Harvey's life and doctrines, in which all the important facts are attractively presented. It is difficult at the present day to discover any new facts connected with Harvey, but Dr. Malloch, at any rate, contributes the observation that, in spite of his name, Wilhelm Fitzer, Harvey's first publisher, was probably an Englishman, who published also works by Robert Fludd and De Bry's "Voyages." We thus come nearer to an explanation of why Harvey chose Frankfort as his place of publication. Dr. Malloch was also responsible for the very useful Catalogue [1] of a Harvey Exhibition held at the New York Academy of Medicine.

INCOMPATIBILITY IN PRESCRIPTIONS.

By SANTOSH KUMAR MUKHERJI, M.B. Calcutta: Rai Saheb B. N. Mukherji and Son. 1928. Pp. 135.

THE excellent intentions of this book are not quite borne out in the result. Possibly a less ambitious treatment of the subject would have saved the author from committing himself to such singularities as the statements that calcium hydroxide is insoluble in water, and that syrup of squill cannot be given with alkalis. Repetition is surely not inevitable in a volume of this size. For example, we read on pages 41, 43 and 45 the statement that sodium bicarbonate is given in combination with diluted hydrocyanic acid. Prolixity, however, is not so serious a fault as inexactitude. Compression under expert advice may produce a revised edition that can be welcomed.

---

[1] Bulletin of the New York Academy of Medicine, 1928, iv., 906.

EPIDEMIC ENCEPHALITIS WITH PREGNANCY, LABOUR, AND THE PUERPERIUM.

By FREDERICK ROQUES, M.A., M.D., M.Chir. Cantab., F.R.C.S. Eng. Manchester: Sherrat and Hughes. 1929. With two appendices. Pp. 139. 15*s*.

SINCE 1917 when in the *Wien. Klin. Wochenschrift* von Economo first described encephalitis lethargica, the literature on this disease has been extensive. It is, however, a curious fact that but little has been written upon it, when complicated by pregnancy, labour, and the puerperium; as far as we know this is the first book that has been published on the subject in any language, an omission doubtless due in the main to the fact that the complication is admittedly uncommon. Nevertheless it was quite time that the omission should be remedied, and Mr. Roques, towards this end, has dealt with the material at his disposal most thoroughly. Starting with chapters on its ætiology and pathology and on the clinical manifestations of epidemic encephalitis in the pregnant woman, the next four chapters deal with the influence of pregnancy on acute epidemic encephalitis and the influence of this disease on pregnancy, labour, and the puerperium. Two chapters on the child are succeeded by two on diagnosis and treatment, the last four chapters dealing with pregnancy and Parkinsonism. The records are given of 40 cases, which have not been published before, placed at the disposal of the author by colleagues, but in order to make his survey more comprehensive, the author has collected from such literature as was available 171 cases in which pregnancy was complicated by acute lethargic encephalitis besides and 23 cases in which pregnancy was associated with the Parkinsonian syndrome.

From a consideration of the material at his disposal, the author concludes that in the majority of cases pregnancy generally proceeds to term without any interruption, that in cases of greater severity premature labour often supervenes, while in the worst cases the patient dies before delivery. Labour differs in that it is painless, and the puerperium is not affected. Other interesting points are, for instance, that neither the age nor the parity of the pregnant woman increases the chance of infection, the mortality is greater when the infection occurs early in pregnancy, and that probably primigravidæ are more frequently attacked than multiparæ. The treatment of the complication is discussed fully and the author is of the opinion that the artificial termination of pregnancy is not indicated, that the second stage of labour should be completed as soon as possible with the aid of the forceps if necessary, and that the mother should not nurse her child. He also issues a warning that the onset of labour should be very carefully watched since, because of its painless nature, the child may be lost. His conclusions on pregnancy and Parkinsonism are that if the onset of Parkinsonism coincides with the onset of pregnancy, labour should be induced. Appendix I. contains full notes of the author's 40 cases, and Appendix II. a list of the cases previously published in medical literature, as regards their age, parity, stage of gestation, and results to the mother and child. There is a full bibliography consisting of 119 references.

Mr. Roques is to be congratulated on rendering a real service to obstetric medicine.

GOULD'S MEDICAL DICTIONARY.

By GEORGE M. GOULD, A.M., M.D. Second edition, revised and enlarged, by R. J. E. SCOTT, M.A., B.C.L., M.D., Fellow of the New York Academy of Medicine. With illustrations and 170 tables. London: H. K. Lewis and Co., Ltd. 1928. Pp. 1522. 30*s*.

THIS book now contains over 83,000 defined words, many hundreds of which are new, and its size exceeds that of the first edition by 125 pages. Dr. Scott states that "the present issue may be said to be the sum of all of Gould's Dictionaries." The parent volume, which appeared in 1894 and was entitled "An Illustrated Dictionary of Medicine, Biology and Allied Sciences," has been familiar for 30 years to all who value precision in medical and scientific nomenclature. A new feature is the inclusion of portraits of medical men who have given their names to operations or tests—a growing practice. This lays the burden on the lexicographer of noting the date of their death, and the fact has been overlooked that Henry Charlton Bastian died in 1915, George Huntington in 1916, Sir William Crookes in 1919, and Vladimir Bechterew on Christmas Day, 1927; while Dupuytren was born not in 1778, but on Oct. 6th, 1777. The eponym of Wilson's disease is misspelt. Help is given in the pronunciation of these proper names: Gould would allow us to call Blaud "blawd," and Glauber "glowber," but Angstrom is to be read "awngstrēm," which we regard as a hardship. While the dictionary is not free from trifling inaccuracies, it contains a wealth of accurate information, admirably displayed, which should make it as popular in its revised form as it was in the old.

THE SACK-'EM-UP MEN.

By JAMES MOORES BALL, M.D., LL.D. London and Edinburgh: Oliver and Boyd. 1928. Pp. 216. 16*s*.

THE author of this book is an ophthalmic surgeon of St. Louis, whose text-book, entitled "Modern Ophthalmology," is popular in other countries besides his own. The historical bent of his mind has already been shown in his monograph on "Andreas Vesalius the Reformer of Anatomy"; under a rather lurid title he now gives a good account, drawn from many sources, of the doings of the body-snatchers or resurrectionists—"its very hard them kind of men won't let a body be." The book is far from being a mere compilation of extracts from the works of others; it contains an excellent epitome of the history of anatomy and the provisions for its teaching in Europe and the United States. As is well known, the legal provisions for anatomical teaching in this country, before 1832, were meagre in the extreme. Even so late as 1830 the founder of one of the last of the private schools of anatomy in England wrote of the difficulties of procuring subjects and the personal risk attached to the office of a teacher of anatomy. Teachers on the Continent were better off in these respects. Naturally much space is devoted to the West-Port murders in Edinburgh a hundred years ago, and to the murder of an Italian boy, in London, by Bishop and Williams, in 1831. Of course Burke and Hare and Bishop and Williams were not "resurrectionists" in the proper sense of the word, but their ghastly trade was made possible by the apathy of the Government in the matter of making proper provision for the teaching of anatomy in this country, and no book on the subject would be complete that did not include a full account of these murders. Warburton's Anatomy Act of 1832, which put an end to body-snatching and to "murder as a fine art," is given in full. The book ends with a short chapter on the teaching of anatomy in America and the New York anatomy riots, and alludes briefly to certain cases of body-snatching which have been perpetrated in the States within comparatively recent times. It is obvious that when describing events which took place at so recent a date (only 50 years ago), the author has to be guarded in his statements; the time is not ripe for a complete review of the circumstances, but it is satisfactory to learn that the officials of the medical college that received the body were exonerated from all responsibility.

A special feature of this book is the wealth of illustrations; the plates are well chosen and excellently reproduced. Some rare handbills, and the title pages of some of the chap-books that flooded Edinburgh

at the time of the Burke and Hare murders, are included in the text and add greatly to its interest and value.

HEINE, THE STRANGE GUEST.

By HENRY BAERLEIN. London: Geoffrey Bles. 1928. Pp. 310. 12s. 6d.

Mr. Henry Baerlein's title has its origin in Matthew Arnold's lines:—

> The spirit of the world
> . . . let a sardonic smile
> For one short moment wander o'er his lips.
> That smile was Heine!—for its earthly hour
> The strange guest sparkled . . . ;

and certainly Heine's life, literary, mental, and spiritual, did make of him a strange guest on earth. We have in this book a discursive story of him, from the cradle to the grave. Born at Dusseldorf in 1797, of Jewish parents, he became more French than many French of the period, through his veneration of Napoleon, with whose most brilliant period his own youth coincided. He failed in Hamburg as a business man, was terribly bored at Göttingen as a scholar, was accepted while still young by the leaders of thought and letters in Berlin as poet and journalist, apostasised from the Jewish religion on practical grounds, visited England where he admired Canning and found Walter Scott wanting, and settled in Paris to make an imprudent love match which, while it lasted, brought great happiness, and supplied him with an unboundedly affectionate attendant through his terribly protracted and fatal illness. This story Mr. Baerlein tells with great fullness of incident in a clear and pleasant way that should lead many who can read German to enjoy the poet's gay and serious phases, his wit, his penetration, and his lovely literary gift.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES, Vol. XXV., October-December.—Dr. C. C. Beatty contributes a paper on Congenital Stenosis of the Œsophagus, in which he has collected and tabulated 50 cases reported in the literature up to 1926, in addition to five examples of the condition which came under his own observation. He distinguishes a membranous type in which there is a partial occlusion of the lumen by a fold of normal mucous membrane, and a non-membranous type in which there is a localised reduction in the size of the œsophagus. The onset of symptoms is usually in infancy, the most characteristic symptom being regurgitation of food a few minutes after deglutition without either pain or nausea. Adult patients may be well developed, but some degree of infantilism is not uncommon in children and adolescents. The prognosis in the membranous type is good, and in the non-membranous type is not unfavourable, as several patients have lived to old age. The best treatment in the membranous form is dilatation by bougies controlled by œsophagoscopy. In the non-membranous form a few successful results have followed radical operation. —In a paper on the Rheumatic Child, based on his study of 400 cases at the Downs Hospital, Sutton, and Queen Mary's Hospital, Carshalton, Dr. N. Gray Hill shows that there are no physical characteristics peculiar to rheumatic children, such as colour of the hair, colouring of the eye, or absence of cutaneous pigmentation, and maintains that the belief that there is a rheumatic type cannot be substantiated. He also brings forward evidence that there is very little, if any, connexion between the life and work at school and the onset of rheumatism or chorea.—Dr. F. Parkes Weber records a case of a "White" Nævus of the Conjunctiva in a Child and a Dark-blue Nævus of the Forehead.—In their paper on Erosion of the Neck Vessels in Scarlet Fever Dr. J. D. Rolleston and Dr. W. Gordon Sears report two fatal cases of this rare complication which they had seen at the Western Fever Hospital in the course of six months. The first was a male infant, aged 11 months, who, in the course of moderately severe scarlet fever complicated by suppurative cervical adenitis and otorrhœa, had profuse hæmorrhage from the ear and died in a few minutes. The bleeding vessel was not identified post mortem, but probably one of the veins in the neighbourhood of the cervical abscess had been eroded. The second case was that of a female infant, aged 2 years, with a septic attack of scarlet fever, also complicated by suppurative cervical adenitis. In this case the hæmorrhage took place from the wound in the neck where the cervical abscess had been opened, the source of the hæmorrhage being the internal jugular vein.—The abstracts from current literature are devoted to ophthalmology.

NORWEGIAN STUDIES IN SYPHILIS.

CRITICISM OF THE RESULTS OF SPECIFIC TREATMENT.

THE late Dr. Cæsar Boeck, professor of dermatology at the University of Christiania (Oslo), has left a tradition which was the subject of a long and interesting discussion at a meeting of the Norske Medisinske Selskap last year. The paper which Dr. E. Bruusgaard read on this occasion is published in *Norsk Magazin for Laegevidenskaben* for December, 1928, and the report of the discussion which followed it appears in the same journal for October.

Prof. Boeck used to arouse many protests among his colleagues on account of his teaching that the so-called specifics, potassium iodide, and mercury, are symptomatic remedies which not only fail to eradicate the disease, but also paralyse the body's natural defences, with the result that the disease runs an atypical course, and inflicts serious injuries on certain internal organs, particularly the central nervous system. Only when the body failed to react satisfactorily, and the disease seemed to run its course unchecked, did Boeck fall back on these two drugs. His colleagues, on the other hand, followed more conventional lines. They taught that mercury must be given in every case, in such-and-such doses, and for so many years. It was, therefore, natural that the generations of medical students brought up in this controversial atmosphere should have been curious to check such conflicting claims in the light of subsequent events. Two of these men have, in their turn, become leaders of the medical profession in Norway, one of them, Dr. Bruusgaard, having succeeded Boeck in the Chair of Dermatology, the other, Dr. S. Dahlström, being chief of the Psychiatric Department of the Ullevaal Communal Hospital in Oslo.

The task which Prof. Bruusgaard set himself was the personal examination of the survivors of the syphilitic patients who had attended Boeck's clinic between Jan. 1st, 1891, and Dec. 30th, 1910. Of the 2181 patients suffering from primary and secondary syphilis in this period, 1388 were women and 793 were men. Prof. Bruusgaard's inquiries into their subsequent fates were begun in 1925 and provisionally ended in 1927. A small number of patients were also examined who had contracted syphilis since 1910, and who had not received specific treatment. On re-examination, the patients were subjected to a very careful examination of the heart, two skiagrams being taken in different planes, and to a routine neurological examination. The cerebro-spinal fluid was examined only in a few cases, but the Wassermann reaction of the blood was carried out in most cases.

After grouping his material in several tables, the first showing the frequency of such complications as iritis and periostitis, the second showing the subsequent careers of the patients whose infection dated back three to four decades, and the following tables showing what happened to the patients whose

infection was more recent, Prof. Bruusgaard summed up his findings as follows :—

From 3 to 40 years after infection an examination was made of 309 patients who were still alive and a study made of the 164 patients who had died, and the cause of whose death was known. Of the total of 473 ex-patients, alive or dead, 131 were clinically symptom-free and gave a negative Wassermann reaction. There were 70 who were clinically symptom-free, but gave a positive Wassermann reaction. There were 67 who suffered from diseases of the blood-vessels, 13 who suffered from general paralysis, and 6 who suffered from tabes. As practically all the cases of general paralysis in Oslo and the neighbourhood are recognised as such and included in the returns, only a negligible quantity being lost sight of, it may be argued that the 13 patients who developed general paralysis represented almost the sum-total developing this disease out of the 2181 patients whom Boeck refused to treat with the so-called specific remedies. In other words, only 0·6 per cent. of all these patients developed general paralysis. While Prof. Bruusgaard took care not to commit himself to a definite opinion on the wisdom of his predecessor's attitude of masterly inactivity, he pointed out that the statistics he had just presented proved very clearly that, in a considerable percentage of cases, the body is by itself able, not only to arrest the progress of syphilis, but even to eradicate this disease. This observation gives support to the modern tendency to combat syphilis by means of non-specific remedies which augment the natural defensive forces of the body —witness the success of the malarial therapy of general paralysis.

Does Specific Treatment Favour Development of G.P.I. ?

In the discussion which followed Prof. Bruusgaard's paper, Dr. Dahlström pointed out that the most commonly accepted computation of the frequency with which cases of syphilis end in general paralysis is about 4 per cent. During the 18 years he had practised as a psychiatrist, Dr. Dahlström had been on the look-out for paretics among Boeck's old patients, but had hardly found any, whereas patients who had been treated with mercury frequently reappeared with signs of general paralysis. Boeck used even to claim that not one of his own patients had ever developed general paralysis, and every time he met Dr. Dahlström he would ask if he had seen any of his (Boeck's) patients suffering from general paralysis. When the answer came in the negative, he would pass on, remarking, " Didn't I say so ! " Among the 320 cases of general paralysis treated at Ullevaal, only two were found to have been treated on Prof. Boeck's principles. Even in these two cases it could not be proved beyond a doubt that they had not been tampered with, i.e., that they had not received mercury from some other doctor. Boeck used to teach that even the smallest dose of mercury made the prognosis worse for the patient. In further confirmation of Boeck's teachings, Dr. Dahlström drew attention to the rarity with which tramps and other light-hearted birds of passage—persons who do not submit to specific treatment—develop general paralysis. It is also rare in the coloured races in their native haunts, but it is not so among negroes living in large towns where hospitals, doctors, and specific remedies are available. Dr. Dahlström also noted that a past record of syphilitic meningitis or cerebral disease does not forecast general paralysis at a later stage. Indeed, among the 95 patients he had treated in hospital with these manifestations of syphilis, he had not seen one subsequently develop general paralysis. This observation did not, of course, refer to those cases of general paralysis which were ushered in by signs of meningitis or lues cerebri.

The Frequency of Syphilis at Necropsy.

Speaking at the same meeting, Prof. Harbitz gave a statistical review of his post-mortem findings at the Rikshospital in Oslo during the 28-year period, 1900–27, in which 6529 necropsies were made. In 369, or 5·65 per cent., definite syphilitic changes were found, and in 303 of these cases (4·68 per cent.) syphilis was regarded as the cause of death. The blood-vessels were involved in 202 cases, the nervous system in 55, the digestive tract in 28, the respiratory tract in 18, the skin in 24 (incidental findings, not causes of death). Amyloid disease was found in 13, severe anæmia in 3 ; the bones were involved in 8, the testicles in 3, and the kidneys in 8 cases. There were also seven cases in which secondary syphilis was an incidental find. The most important point to note in these findings is the predominance of the blood-vessels and the central nervous system as seats of syphilis that proves fatal. And syphilis of the arteries and heart was three to four times as common as syphilis of the central nervous system. With regard to the suggestion that tertiary visceral syphilis has increased in frequency, Prof. Harbitz had grouped his material in two 14-year periods. In the first, 1900–13, there were 3272 post-mortem examinations, among which syphilitic changes were found in the organs in 214 cases—i.e., in 6·54 per cent. In the following 14-year period, 1914–27, there were only 155 such cases among 3318 necropsies—i.e., only 4·82 per cent. Prof. Harbitz added that his post-mortem findings must be regarded as representing only a fraction of the total number of syphilitics examined post mortem.

The Expectation of Death of the Syphilitic.

During the same discussion, Dr. E. H. Hansteen produced some interesting figures wherewith he calculated the chances of syphilitics dying of their disease. His material consisted of the post-mortem records of the Ullevaal Communal Hospital in Oslo in the period 1907–25. Among the 11,477 post-mortem examinations there were 465 cases in which definitely syphilitic changes were found in adults (acquired syphilis) and 50 other cases in which the changes found were probably syphilitic. This gave a total of 515 cases—i.e., an incidence of 4·49 per cent. In 247 cases syphilis was the cause of death (2·17 per cent.), whereas in 268 other cases (2·32 per cent.) syphilis was an incidental find and not the principal cause of death. Among the 247 fatal cases of syphilis, there were 161 in which it was located in the heart and vascular system, 72 in the central nervous system, and 1 in the liver. There were three cases in which it gave rise to general amyloid disease. Also, in the 268 cases in which syphilis was an incidental finding, the structures most often involved were the heart and blood-vessels. In the same period congenital syphilis in infants was demonstrated in 101 cases ; it was the cause of death in 72, and an incidental finding in 27. There were also two cases of late congenital syphilis in adults. If the cases of acquired syphilis be added to the congenital forms of the disease, there is a total of 616 cases (5·36 per cent.), of which 321 (2·78 per cent.) proved fatal on account of this disease. Assuming that the 11,477 persons examined post mortem at the Ullevaal Hospital were a representative sample of the population of Oslo, Dr. Hansteen proceeded to make the following calculation. With a population of about 250,000, and an average annual death-roll of 2700, there must have been approximately 59 deaths every year from acquired syphilis. The notifications of acquired syphilis in Oslo range from 400 to 900 a year, the average for the period 1907–25 being 627. To this average Dr. Hansteen added about 30 per cent. in order to make good the new cases of syphilis which elude notification. By this means he arrived at a total of 836 new cases of syphilis every year. As approximately 59 persons die every year of acquired syphilis in Oslo, the calculation is made that 7·06 per cent. of persons contracting syphilis will ultimately die of this disease. The actuarial value of this calculation is, of course, impaired by the element of guessing in it, but it remains nevertheless a useful starting-point for similar investigations and calculations by other pathologists.

THE LANCET.

LONDON: SATURDAY, JANUARY 19, 1929.

THE KING'S ILLNESS.

FOR the first time for seven weeks HIS MAJESTY'S lness is not made in this column the subject of an fficial bulletin, a fact which proves how correct have een the prognostications of his advisers when they ere able from time to time, in the most cautious rms, to report some progress. There is no doubt iat the regular bulletins, containing information iade up of the salient facts for those who could ppreciate them in their proportions and inter-elations, have been extremely valuable to the KING'S nxious subjects. Never has it been disguised for a ioment that HIS MAJESTY was seriously ill; never as the temptation to allay widespread apprehension een yielded to, so that undue stress was laid upon ven undoubted steps towards recovery. Void of hetoric, and in as simple phraseology as the language f science permits, the story has been told from week o week in the right way.

The bulletins since the last issue of THE LANCET ave been signed by Sir STANLEY HEWETT and Lord)AWSON, two only of them carrying also the signature f Sir HUGH RIGBY, whose silence implies a satis-actory issue to surgical interference. The bulletins ell the same story of very slow progress, a "quiet ay" and a "restful day" culminating in an affirma-ion that HIS MAJESTY continues to make slow rogress. No medical man will fail to appreciate how nxiously the patient must continue to be watched hrough an extended period of time, for an illness o prolonged and so severe must always leave the ubject liable to an addition of exhaustion which has hroughout been dangerously pronounced. That is to ook upon the gloomy side; but at the long last we nay permit ourselves to indulge in happy anticipations f convalescence.

TRAINING IN BIOLOGY.

Two leaflets issued last week from the Ministry of griculture and Fisheries lay stress on a large and rowing demand, existing throughout the British mpire, for men trained in biology. The new propa-anda is, as would be expected from its place of origin, rgely concerned to point out the need, alike at home nd in our colonies, for biologists to combat insect nd fungoid diseases, to breed improved varieties of rops, to advise on livestock and its breeding while nproving meat and dairy produce, to fight animal iseases, and to provide scientific information in respect of the storage and transport of agricultural products. The Ministry suggests that there is a lack of facilities in our schools and universities for the training of biologists fit to discharge such duties, and that there is a dearth of school teachers able to impart knowledge of a branch of science which many persons to-day would consider to be a desirable part of the regular school curriculum. In both leaflets tabular statements occur which testify to the increase of research and advisory service, for England and Wales, that has been financed by the Ministry of Agriculture in the last ten years, the experience of Scotland being similar. The number of posts available and, at the same time, the demand for biological research has grown more acute year by year, and the opportunities for the employment of special biological equipment continue, and will continue, to expand. The message from the Ministry of Agriculture and Fisheries is a practical one, being—Here are openings for useful employment which are not being filled, and men are not being trained to fill them in sufficient numbers.

The Ministry of Health and the General Medical Council will be in accord with this message, for the training of the medical student in biology presents in many places a difficult problem, adequate opportunities for teaching not being forthcoming. In speaking of medical education, it is true, we are thinking of biology only in simple terms as a school subject; the ground-work must be done, while consideration may be left aside of the many directions in which biological research of the most highly specialised character plays its part in therapeutics. Biology, physics, chemistry, and biochemistry are the fundamentals of the medical curriculum, a proper acquisition of which must be obtained if anatomy, physiology, and, in due course, the principles of pathology are to be mastered; and a dearth of instruction in biology has produced a definite difficulty in medical education. Whether any change of policy may have to be adopted by the General Medical Council for lightening the burden of our medical curriculum, or whether the existing pattern be retained, it must be equally embarrassing that, of the three great preliminary subjects, one cannot be taught with facilities proportional to those provided for teaching the others. And it is doubtful whether we fully recognise, in the education of medical students, the high significance of training in biology, a default which an address [1] by Dr. F. A. E. CREW, Professor of Animal Genetics at Edinburgh, should remedy. Speaking on the position that biology should occupy in education, Prof. CREW points out that general education should be concerned with "the development of the art of living, with teaching the developing individual how to think and how to feel and how to seek and gain opportunities for exercising these faculties." Following on this definition, he points out that as the scholasticism of the Middle Ages gave way to the humanism of the Renaissance, so the *literæ humaniores* must give way to education in science, for he believes that science could replace in the school curriculum,

[1] Nature, Jan. 12th, 1929, p. 54.

and replace adequately, the humanistic philosophy of life. This thesis he supports eloquently, pointing out that biology has progressed towards the method of experimental analysis, while its conclusions are based increasingly upon experimentation, so that biologists speak of facts that cannot be denied any more than their connexion with the welfare of mankind. Thus firmly set upon its foundations biology becomes a fitting school subject.

Medical men want no convincing that biology could be included in a normal school curriculum with great advantage to pupils of all sorts—it is precisely that omission which introduces the difficulty for the General Medical Council in deciding how far the overcrowding of the medical curriculum could be relieved at the beginning of the course. It is clear that those who have charge of medical education cannot ask students of medicine before registration to satisfy them that they possess a standardised knowledge of biology, while many of those students cannot obtain a practical opportunity of studying the subject at all, and the gap has still to be filled by classes in the medical school itself. But if biology should thus take its place in the general scheme of education, the greatest pains must be taken to avoid, in the early stages of inculcation, any approach to specialism. The subject will have to be taught as the background of zoology, botany, and physiology, and also as one that requires the assistance of chemistry and physics for the appreciation of its phenomena.

NEUROSIS AND WORK.

A DISCUSSION on mental hygiene, reported in THE LANCET of Jan. 5th, brought from Dr. EDWARD MAPOTHER a comment which emphasises the existence of diametrically opposed modes of treatment of the neurotic or the neuropath. Is he to be shielded from stress and have his life made easy for him, or is he to be taught the doctrine of courage and made to struggle against the risk of breakdown? Dr. MAPOTHER upholds the second alternative, and notes with undoubted truth that much of the best work of the world is done by potential neuropaths putting up a great fight against the risk of a breakdown. PIERRE JANET, who still stands unrivalled as a clinical observer, is less hopeful, and with many patients adopts the attitude that their *tension psychologique*—or vital urge, as we might call it—is so low that their life task must be adjusted to it. Yet another aspect is to be found in Sir JOHN GILMOUR'S address at the Annual Congress in St. Andrews of the Scottish Education Institute, when he warned students against the danger of breakdown from educational over-pressure, and made the shrewd observation that girls do not always succeed in treating the demands of learning with the philosophic calm which boys are able to command. His theme has been given popular expression in the saying, "If you give a girl too much to do she'll break down; if you give a boy too much to do he won't do it." Often enough the clinician, dealing with adult breakdowns ascribed to overwork, is told that the overwork was unnecessary, that the patient drove himself harder than he needed; in short, that he overworked because he was neurotic. JANET made a group for such cases, giving them the title of *les scrupuleux*, and it is not sufficiently recognised that many nervous people are overscrupulous, over-critical of themselves, and a prey to a restless urge to perfection that can never be reached. In the same person these qualities can lead to brilliant and original work or serious breakdown, or both. The symptoms often fall into the category of obsessional states, and Miss MAY SMITH and Dr. MILLAIS CULPIN, working for the Industrial Fatigue Research Board, have made the observation that these subjects produce results on the MacDougall-Schuster dotting-machine that cannot be approached by any subjects free from nervous symptoms. It is neurotics of this type whose life is too often ruled by the proverb that what is worth doing is worth doing well. For them such counsel is pernicious; they rarely need urging to further exertion, and require rather advice on saving themselves from those introspective criticisms and doubts which, when exaggerated, form the pattern of their nervous breakdowns.

The position of the sufferer from pathological anxiety is different. Though it must not be supposed that there is a clear diagnostic line between the two types, certain distinguishing features may be recognised. The people described above may suffer acutely from anxiety in certain situations—as when alone, or in a crowd, or on a height, according to their individual phobia—but usually have no bodily symptoms, not even a rapid pulse, except when they are actually struggling against an obsession. The patient with anxiety neurosis, on the other hand, will often exhibit physical symptoms ranging from palpitation and sweating, to indigestion and headache, and has nearly always a rapid pulse. The latter type, whose anxiety is unfitting to the circumstances and arises from sources in his unconscious, must often, in the absence of facilities for psychological treatment, be counselled to admit the existence of his troubles and carry on his work in life with such extra effort as would be necessary with a physical disability. The research workers mentioned above have distinguished between neurotic symptoms and neurotic disability, for in some manual occupations people were found doing good work without nervous breakdown, in spite of the presence of severe anxiety symptoms. It must, however, be emphasised that the symptoms remained; nothing in the work stimulated them, but we may suppose that a less fortunate choice of occupation would have resulted in disability. A great amount of sickness results from anxiety states or physical conditions arising out of them, and it is only by a close study of each case that one can strike the right balance between allowing the patient to give way too readily and failing to recognise when his symptoms make work impossible. A pitfall always to be avoided is the easy assumption that hard work per se can cause nervous breakdown, an assumption contrary to all modern psycho-pathology. Worry often arises from causes within the patient rather than from external working conditions, and it is a human failing to turn aside from the consideration of inner troubles if something external can serve as a scapegoat. Neurotic symptoms are a sign of disharmony, of maladjustment to the demands of life, and if external stress exacerbates them, they may serve as a means of escape from that stress; they are, nevertheless, real to the sufferer, as real as any more obvious physical disorder, and to deny this reality is an elementary error that deprives the one who makes it of any influence he might otherwise possess. To understand the reality is to go far towards attaining that coöperation with the patient which will enable us to give him courage to bear the stress of life or to make such reasonable concessions and adjustment as his emotional difficulties require.

BRONCHO-PNEUMONIA.

THE threat of influenza, which cannot be overlooked, makes the problems of broncho-pneumonia, especially when young subjects are attacked, of particular interest. Each year, as winter proceeds, the practitioner has to grapple with a number of cases of acute respiratory disease. Although most of these are of the minor kind, typified by the "common cold," which causes merely a few days' discomfort to the individual, they provide the source of infection for a large number of serious cases of broncho-pneumonia. The public finds it difficult to believe that the cause of the common cold is still unknown and, indeed, it seems curious that we cannot ascertain whether the bacteria commonly found—pneumococci, streptococci, *B. influenzæ*, *M. catarrhalis*, *B. septus*—are primarily responsible, or are secondary associates of an undiscovered filterable virus. There is general agreement, at any rate, that the more serious complications, such as broncho-pneumonia, are caused principally by the pneumococcus, streptococcus, and influenza bacillus in varying combination. In recent years the influenza bacillus and the hæmolytic streptococcus appear to have played a prominent rôle. Acute lobar pneumonia has not the same close relation to these minor infections as broncho-pneumonia. Its seasonal incidence is different, and the well-defined virulent types of pneumococci which cause the majority of cases are not those found in the milder catarrhal infections. Nevertheless the pneumococci of lower virulence, which in an adult may only cause a simple coryza, can be responsible for pneumonia in weakly subjects and children.

We cannot yet distinguish clinically and bacteriologically between harmless colds and those which may become dangerous. Probably there is no essential difference, and the result depends upon the relation between the size of dose of the infection and the individual resistance. The term "influenzal cold," though loosely used, is popularly supposed to denote a graver condition than a simple cold, and there is something to be said for its application to a type of cold which closely resembles and is probably often identical with the simple influenza seen during epidemics. It is characterised by a more abrupt onset, a higher temperature, more severe headache, greater aching in the back and limbs, and a drier catarrh. Experience shows that such colds are more likely to show spread to the lower respiratory tract, the danger sign being the appearance of râles, coarse, medium, or fine, scattered through the lungs, especially in the lower lobes. These signs indicate bronchiolitis, which is the essential lesion of influenza. They are apt to be very persistent, and so long as they exist there is a possibility of broncho-pneumonia. Infants under 3 to 4 months old who get a nasal catarrh almost invariably have an extension to their bronchi and often a broncho-pneumonia. An infection which may be negligible in an adult can cause fatal disease in a young child who has not yet been immunised by frequent sub-morbid doses of infection. In spite of every care broncho-pneumonia may arise in patients who apparently have a mild catarrh; but undoubtedly strict observance of the rule that a febrile patient must stay in bed would do much to prevent complications. Patients should be kept in bed until the temperature has been normal for 24 hours or, in more severe cases, until all râles have disappeared. When broncho-pneumonia supervenes the signs may appear on the third or fourth day without any previous drop in the temperature, or they may occur after apparent recovery four to ten days later. Fulminating cases, with lung involvement from the first, are not so often seen in inter-epidemic periods.

We know no drug which will check an influenzal cold, and it is difficult to improve upon the old-fashioned remedy of promoting profuse perspiration by a hot drink of lemonade, with or without whisky, and grs. 10 of Dover's powder, and going to bed with a hot-water bottle and extra blankets. Abundant fluids should be taken, up to 4 or 5 pints a day, and as there is no desire for food the addition of glucose, 1 lb. to each 3 pints of lemon water, will provide all the nourishment needed by the patient. With any sign of lung involvement absolute rest, physical and mental, must be insisted upon. Too often the patient is allowed to get up for excretory purposes so long as he is physically able to do so, but in spite of protests the doctor should be adamant upon this point. The nurse must anticipate the patient's wants and refrain from fussiness. Much unnecessary exertion is caused by reaching out for drinking vessels and sputum mug, by routine washings, and removal of garments. A single garment, slit down the middle, light bed clothes, and a cool room will help the patient to lose heat. Windows should be open day and night, but the need for fresh air should not expose the patient to icy draughts or glaring sunlight. The patient is thirsty rather than hungry, and glucose lemon-water should be taken freely. With this milk can be reduced to 1 pint a day. There is still a misplaced confidence in beef teas, but their nutritive value is magnified and they may be objectionable on account of the amount of extractives they contain. Careful attention to the cleanliness of the mouth will add to the patient's comfort and safety. Three grains of calomel at the onset, followed by a saline, may be given, but thereafter a soap-and-water enema on alternative mornings will suffice. The pain of pleurisy may require strapping, antiphlogistine, poultices, or leeches, but they should not be continued after pain has ceased. A Dover's powder will relieve pain and sleeplessness, and opiates can be continued so long as the bronchi are clear and there is no cyanosis; otherwise all drugs that cause sleep are dangerous.

Undoubtedly the hope of lowering the high mortality from the pneumonias lies in the discovery of some form of specific treatment. Specific chemotherapy has so far failed in connexion with bacterial infections. The use of vaccines has not yet been generally accepted, but the records of those who have used them extensively are undeniably good. As with all methods of specific treatment they must be used as early as possible. Their object is to control the infection at the beginning and prevent dangerous developments; they can give little or no assistance when toxins, maybe in fatal doses, are already fixed in heart and nerve cells. The vaccine which has been most used is one containing equal numbers of pneumococci, streptococci, and influenza bacilli, and a suitable dose for an adult is 100 millions of each organism, though much larger doses can be given with safety. With such treatment given within the first 24 hours from the onset in a large proportion of cases, it has been shown that the temperature falls to normal within the following 24 hours, but with each day's delay less striking results are obtained, and when injection is delayed until the fourth day the results are little influenced. The immediate action of the vaccine is non-specific, but specific antibodies are produced later and add to those formed naturally. As specific antibodies are not present for several days, the patient is unsensitised and no negative phase supervenes. It is the fear of the

negative phase which has hindered the use of vaccines in acute infections. In chronic infections specific antibodies are present, the patient is sensitised, and reactions are easily produced, so that when vaccines are used for delayed resolution in pneumonia, or are not used until the patient has been ill for more than five days, caution is required, and the initial dose should be small—for example, 5 millions. The early administration of vaccine necessarily entails early diagnosis. The abrupt onset and striking symptoms of lobar pneumonia should make its recognition possible before consolidation occurs, but with broncho-pneumonia the onset is often insidious, and the fact that a case has taken on a graver aspect is not always recognised at once. It is not, however, necessary to wait for undoubted signs of pneumonia, since injection in the prepneumonic stage will, in most cases, cut short the infection and prevent the onset of the grave complication.

With early specific treatment, absolute rest, and fresh air, much can be done to prevent circulatory failure, the treatment of which occupies so much space in text-books. The heart is best helped by feeding it, and the best foods are oxygen and glucose. With the slightest indication of cyanosis, oxygen must be freely administered through a nasal catheter or with a mask. The futile method of the funnel, however, still survives and brings oxygen treatment into discredit. When circulatory failure occurs the patient is in a parlous condition. One by one the drugs upon which we formerly relied have been discredited, and the difficulty of treating poisoned organs incapable of response is now recognised. The seat of circulatory failure has passed with our increasing knowledge from the heart to the medullary centre and the capillaries. When the heart is at fault adrenalin is the most useful drug since it augments and accelerates its contractions. For capillary dilatation pituitary extract is available, and when failure of the vasomotor centre occurs strychnine has a certain limited field. Alcohol, the most popular of all drugs in pneumonia, has a fleeting reflex action upon the heart from irritation of the mucous membrane of the mouth and stomach, but after absorption it has no apparent action upon the heart or blood pressure and it is difficult to see how its action in increasing the flow through the skin at the expense of the internal organs is required. Circulatory failure is a complicated matter, and it is at present impossible to assess the various factors concerned, each of which requires a different line of treatment. Our hope lies in the prevention of circulatory failure and not in its treatment.

Convalescence may be a tedious matter and râles a long time disappearing, but the patient should not be allowed to pass from care until the chest is clear. Chronic fibrosis is perhaps the commonest chronic lung disease, and the most frequent cause is a broncho-pneumonia. Much future ill-health could be prevented by greater care during convalescence, and the lungs after broncho-pneumonia should be as carefully watched as the heart after acute rheumatism.

INTERNATIONAL HOSPITAL CONGRESS. — This Congress will assemble at Atlantic City, New Jersey, U.S.A., on the morning of June 13th. It will be immediately followed by the annual convention of the American Hospital Association. The Congress is the first of its kind and in connexion with it there will be an exhibit of plans and models of modern hospitals, of various types of hospital equipment and supplies, and of statistical data relative to the care of the sick throughout the world. The purpose of the Congress is to bring together those interested in hospital administration, construction, and organisation.

Annotations.

"Ne quid nimis."

CONDITIONS OF CHILDBIRTH IN INDIA.

THE disturbance created by Miss Mayo's book "Mother India," has by no means died down, and acrimonious controversies arise from time to time over one or other of its criticisms of Indian social life. It is not our purpose here to reopen any general discussion of the merits of this work, but an article by Miss Eleanor Rathbone in a recent *Hibbert Journal*, entitled "Has Katherine Mayo slandered 'Mother India,'" lays especial stress on her remarks on childbirth, and it seems worth while to consider what the present position really is, and whether any practical means of improvement exist or can be introduced. That there is abundant evidence of very excessive mortality of both mothers and infants must be at once conceded. Indian vital statistics are notoriously inaccurate, but as Miss Rathbone points out, any error in the calculated death-rate can safely be assumed to lie in the direction of deficiency rather than excess. When, therefore, it is stated on good authority that a maternal mortality of 20 per 1000 births is a very conservative estimate we may regard the figure as certainly not an exaggeration of the facts. It has to be compared with a British figure of between 4 and 5 per 1000; similarly the infant mortality of about 300 per 1000 for urban and 175 for rural districts in India compares unfavourably with a general rate of 70 for England and Wales and 35 in Dunedin, New Zealand. These figures leave so large a margin for any possible error that they can be allowed to speak for themselves. Besides, the main proposition has long ago been conceded by the leading Indian reformers themselves.

The causes of this sad and discreditable state of things are not far to seek, for anyone with experience of Indian maternity work knows that the conditions under which labour occurs—with comparatively few exceptions amongst the more prosperous and better educated people of the towns—are truly appalling. This is a matter on which Miss Mayo could hardly have exaggerated, even had she intended to do so. When she says that the lying-in woman, being conventionally unclean, is installed in the darkest and dirtiest closet available, and provided with filthy rags that have been specially set aside for her use, that air and light are carefully excluded and the room is filled with the fumes of a charcoal brazier; that the *dai* or hereditary midwife in attendance is not only illiterate but notably dirty in her person, and regardless of the most elementary rules of cleanliness; and that the patient's diet is on starvation lines and utterly unsuitable—when she says all this, and also points out that the mother is herself usually the product of an early marriage, and often of the purdah system, she is only stating what is a commonplace to every practitioner in India. All these factors react more or less on the infant as well as the mother, and what chance it has of making good is still further weakened by its being fed on poor breast milk, or over-diluted cow's milk drawn and kept under more than doubtful conditions, and often also by the administration of opium to still its cries of hunger and pain. The purdah system coupled with a general defiance of every law of hygiene, is also responsible for more than vague ill-health. Osteomalacia and rickets are common, as one would expect, and the zenana is naturally a hotbed of tuberculosis. What, asks Miss Rathbone, in effect, can be done to secure the mitigation of these and other similar ills in the future? And must not Westerners, who have been responsible for the government of the country for so long, take blame to a certain extent for their continuance?

There has certainly been a tendency in the past to accept Indian social customs as inevitable, and to disclaim responsibility for their perpetuation, and so

ar we believe the British administration must bear s share of the discredit. The official efforts that have een made to improve maternity conditions have in he past been mostly feeble and sporadic. In the last alf century, however, some significant changes have ccurred, in this as in other social departments. The 'arsees of Bombay are, of course, not actually Indian n origin, but they have assimilated many Hindu ustoms, and their communal life is still largely lominated by a comparatively illiterate priesthood. n spite of this, however, and the violent opposition ie at first encountered from a large proportion of his ompatriots, the campaign initiated by Sir Temulji Nariman, M.D., for the introduction of modern naternity measures, has long ago been brought to a riumphant conclusion, and the Parsees, who used to e as archaic as the Hindus in this respect, have now is good obstetric facilities as any community in the vorld, and make use of them to the full. This advance could not have been made without a parallel introduc- ion of education, particularly for the women, and Miss Rathbone justly observes that this is the irst and most pressing need of India. Along with this general educational movement must go he supersession or training of the *dais*. It has been the fashion until recently, particularly amongst he medical profession, to contend that the attempt to make them into responsible assistants to deal with the *dai* is hopeless. We think this view s wrong. India, in spite of the legendary pagoda tree, is a poor country, and to wait for an ade- quate supply of midwives trained on conventional lines would be to wait for a very long time. The *dai* is an awkward problem, but experimental schemes on a small scale have lately shown that it is not impos- sible to persuade her to undergo short courses of practical training which, in successful cases, convert her from a deadly menace into a useful adjunct of village life. Rural midwifery presents a task whose very fringe the regular nursing profession will never be able to touch, and the regularisation of some inferior maternity agency, such as the *dais*, is even more necessary than the provision of elementary medical aid in the smaller villages, where fully qualified doctors are not available. The establish- ment of infant welfare centres in the larger towns has already done much to open up the allied question of antenatal instruction and to supplement the work of the hospitals as regards infants and young children, and the same principle might with advantage be extended to the districts, where it would be a valuable reinforcement to the existing medical agencies.

OPERATION FOR CONGENITAL STENOSIS OF THE BILE-DUCTS.

WHEN there is congenital abnormality of the bile-ducts the smallness of the structures involved and the associated jaundice have usually deterred surgeons from operating, and comparative failure seems to have attended the efforts of those who have made the attempt. But a fresh stimulus to the surgical treat- ment of this condition is given by the work of W. E. Ladd,[1] of Boston. He operated on 11 out of a series of 20 children with narrowing of the ducts, and found that eight were suitable for surgical treatment, six of whom recovered. These six include one infant of 3 months with atresia of the common duct, for which choledochoduodenostomy and cholecystostomy were performed; one of 5 months with the same abnorm- ality which was cured by cholecystgastrostomy; one of 3 months with stenosis of all three ducts, successfully treated by cholecystostomy and dilatation with a probe; and one of 4 weeks in which obstruction of the common and cystic ducts was relieved in the same way. In the other two cases partial obstruction of the common ducts was satisfactorily treated by chole- cystduodenostomy, but the patients were 5 years old, and the condition hardly seems to deserve the term congenital stenosis of the bile-ducts as it is understood in the literature. As Ladd remarks, both the nature and degree of abnormality vary considerably, so that different operations are necessary in different cases. For small infants with an obstructed common duct he recommends anastomosis of the common duct to the duodenum over a catheter, pointing out that introduction of a catheter into the duodenum through the gall-bladder and common bile-duct is an important part of the technique, as it ensures patency of the anastomosis which is otherwise difficult to obtain on account of the smallness of the structures. He thinks that operation is desirable as soon as the diagnosis seems reasonably certain, before there is wasting or concurrent disease, and he says it may be undertaken with expectation of success in any case in which either the common duct or the gall-bladder has a patent connexion with the liver. Only those who have seen such cases in life and examined the structures at autopsy can fully realise the technical difficulties of the operations which he advocates. But the fact that inactivity means certain death, while intervention evidently can be successful, undoubtedly justifies his plea that it should be tried more often. It will be interesting to learn the subsequent history of the cases operated on successfully.

THE ÆTIOLOGY OF PELLAGRA.

IT is now more than a year since the fact was established that vitamin B is a dual entity, of which one part only, now called vitamin B 1, represents the previously recognised antineuritic or anti-beri-beri factor. The two factors have a somewhat similar distribution among foodstuffs, and yeast is particularly rich in both. Since yeast in some form has been almost universally used as the source of vitamin B in dietary experiments, it has come about that nearly always the two factors have inadvertently been given together. The second factor, vitamin B 2, has been further protected from discovery by the circumstances that, in experiments on the rat, when both factors are withheld the animal always succumbs first to the neuritic symptoms, and dies before any sign of the second syndrome has time to develop. In other words, the reserve of vitamin B 2 always outlasts that of vitamin B 1, when neither vitamin is offered in the food. H. Chick and M. H. Roscoe [1] found, last year, that an alcoholic extract of yeast, in which vitamin B 1 alone is present, cures the neuritic symptoms and keeps the rat alive until the second deficiency has time to manifest itself. The latter is marked by ophthalmia and skin symptoms —i.e., loss of hair and a characteristic dermatitis on paws, ears, and neck. The most interesting feature of the discovery lies in the identification, by J. Goldberger [2] and his colleagues, of this syndrome with the well-known disease of pellagra. They have proved that pellagra in man may be cured and subsequent relapses prevented by the administration of dried brewers' yeast, as well as by a number of other foodstuffs. They used a commercial prepara- tion of the Harris Laboratories, Tuckahoe, N.Y., at first in a daily dose of about 50 g.,[3] but later 15 g. was found sufficient.[4] In the outbreak of pellagra which followed the deprivation caused by the Missis- sippi floods,[5] yeast was prescribed as the routine treatment, with canned salmon, beef, or tomatoes as an alternative. The ætiology of pellagra is not, however, completely cleared up by these experiments, since the exact relation of pellagra to maize-eating is not yet fully established. The disease occurs on a large scale entirely in maize-eating countries, but it is not yet known whether the whole maize grain is pellagra-producing or whether only a certain fraction,

[5] Goldberger and E. Sydenstricker: Ibid., 1927, xlii., 2706.

left after milling, is responsible, as in the relation between rice and beri-beri. It should be easy to ascertain whether vitamin B 2 is present in maize, before and after milling. It is curious that some maize-eating communities, such as certain natives of South Africa, do not suffer from pellagra. The explanation of their immunity remains to be worked out; it may be traceable to a different process of milling. Whatever the exact circumstances contributing to its causation, the prevention of pellagra in man is in sight. The disease, like beri-beri, will be stamped out as soon as it is realised that it is poor economy for a State to allow its citizens to suffer from a disease which can be avoided by the provision of a more adequate diet.

BAYLISS-STARLING MEMORIAL FUND.

MANY of our readers will remember that an appeal was issued last year (see THE LANCET, 1928, i., 718) for subscriptions to provide a memorial to the late Prof. Sir William M. Bayliss and Prof. Ernest H. Starling. We learn that the results of this appeal have been such as to enable the committee to fulfil the objects which they had in view. The sum collected will, apart from subscriptions which are still arriving, amount by the end of January to something over £2600. Large contributions have been made by physiologists abroad, particularly in America and Germany, and from many distinguished members of the practising side of the medical profession. The Memorial Fund Committee wishes it to be made known how the sum raised will be disposed of. A small part of it has been employed in the preparation of a simple memorial tablet in bronze. This, which has been designed by Prof. A. E. Richardson, F.R.I.B.A., bears the words :—

WILLIAM MADDOCK BAYLISS, F.R.S.
1860 1924

ERNEST HENRY STARLING, F.R.S.
1866 1927

It is proposed to erect it in the entrance-hall of the department in which they spent so many fruitful years, where it will occupy a suitable place above the bust of William Sharpey. Most of the money, however, will shortly be transferred to the University of London to be held in trust for the creation of a Bayliss-Starling Studentship, the object of which will be to enable a selected graduate in science, or graduate or undergraduate in medicine, of suitable standing, to spend a year or more in acquiring a knowledge of physiology and biochemistry preparatory to commencing research work in that subject.

ULTRA-VIOLET LIGHT IN MENTAL HOSPITALS.

IT has become the custom to regard the provision of ultra-violet ray apparatus as a sign of progress in mental institutions, and to assume that committees which have the welfare of their patients at heart will add this form of therapy to their equipment. Its use is, however, still limited, as shown by the recent inquiry of the Actinotherapy Subcommittee of the Royal Medico-Psychological Association. A letter addressed to 200 mental hospitals elicited 47 replies, from which it was learned that 16 institutions had ultra-violet apparatus and eight more hoped to have it soon. The discussion on the subject at the Section of Psychiatry of the Royal Society of Medicine on Jan. 8th showed that the medical staff of mental hospitals who have had actual experience of "artificial light" are convinced that it is justified. If there are any to whom irradiation has proved itself a failure, they did not attend to put their experiences before the meeting. With certain reservations as to selection of cases and administration by experienced physicians—reservations which apply to this treatment in all forms of disease—the psychiatrists present agreed that real benefit had been obtained by their patients. Dr. Dove Cormac reported, on four years' experience of ultra-violet light at Parkside Mental Hospital, that the patients had shown a marked increase of body-weight, improvement in appetite and muscular activity, a slight average decrease in blood pressure, and distinct exhilaration. He held that, while the treatment was bad for hyperthyroidism and melancholia with agitation, it undoubtedly curtailed the depressive period in the manic-depressive psychosis, benefited mild melancholia and anergic stupor, and rendered the delusional patient more amenable and his delusions less dominant. He had found the carbon arc better than the mercury-vapour lamp. With his conclusions Dr. A. C. Hancock, of Barming Heath, agreed, laying particular stress on the value of local applications for septic foci. Sir Henry Gauvain gave an interesting account of the effects of heliotherapy at Alton on the minds of disabled children. Marked improvement was observed both in "mental age" and in cheerfulness. Dr. G. de M. Rudolf, of Claybury, sounded a warning note by exhibiting a weight chart extending over several years and showing periodic rises. Had only a small part of this chart been available, one of the rises might well have been attributed to the ultra-violet light treatment.

Another aspect of the problem was stressed by Dr. R. Bourdillon, who pleaded for "more light and less invisible radiation" in actinotherapy. The September midday sun in temperate latitudes at sea-level gave half a gramme-calorie of visible light per square centimetre per minute, whereas a patient standing three feet away from a mercury-vapour lamp received only one-hundredth of a gramme-calorie. Therefore 15 minutes of a mercury-vapour lamp was in this respect equal to 18 seconds of September sunlight. He urged that exposure to the mercury lamp should be called ultra-violet treatment and not light treatment. The carbon arc approaches more nearly to sunlight, but varies enormously according to the particular electrodes and other factors. Very little is known, continued Dr. Bourdillon, of the effects of ultra-violet rays, because they have so seldom been administered unmixed, but they certainly lead to the production of antirachitic vitamin D and they burn the skin. The vitamin D can be much more cheaply and easily provided by the oral administration of irradiated ergosterol, while the value of burning is difficult to appraise in general treatment though incontestable in some skin diseases. The visible and near infra-red rays certainly penetrate more deeply. The magnificent results of heliotherapy in surgical tuberculosis are undoubted, but here the effects of ultra-violet rays have not yet been accurately distinguished from those of other factors such as cold air. There was reason to fear that the great utility of ultra-violet radiation in some diseases had caused undue neglect of the even greater value of radiations of longer wave-length for general treatment. Dr. W. A. Potts admitted in the discussion that he had obtained very much better results in hospital patients than in private patients, and he ascribed this to the fact that light treatment in a hospital was a kind of social outing. The nervous patient was reassured by the "old hand," and the particularly depressed patient was always put next a cheerful one. Dr. Albert Eidinow pointed out that the mercury-vapour lamp was designed expressly for acute and subacute disease, to produce a rapid effect and the maximum change in the blood, and that these diseases could not be treated with lamps that gave out a great degree of heat. In mental diseases, as he said, we have a totally different problem and need quite different radiations. The chronic case calls for longer radiation and heat, a pleasant, warm, practically non-erythema-producing light, perhaps best supplied by a very powerful tungsten filament.

There is clearly a difference in outlook between the physician whose object is to improve the health

of his patients in any way possible, and the research worker whose aim is to further knowledge by accurately controlled tests. The mental hospital physician takes a lamp, groups a dozen patients round it, finds that they improve physically and mentally, and that their convalescence is hastened, and declares that ultra-violet light is a valuable factor in the treatment of mental disease. The physical chemist points out that three-quarters of the rays he is using are not ultra-violet at all, that the patients are receiving other kinds of treatment as well, and that many purely psychological factors come in. It is, however, for the scientific worker and the clinician to meet together and to clear up ambiguity, and there is urgent need for research to this end. Till the nomenclature is cleared up no one would deny to the clinician the right to administer and to extol a technique which in actual fact appears to him to do his patients good. The general conclusion seems to be that at the present stage—after all, a very early one—artificial sunlight treatment, particularly the carbon arc, is a good therapeutic measure for mental patients, even though its exponents have not yet distinguished between the various factors which may be responsible for the results obtained.

CHEMICAL WARFARE.

TEN years have passed since the war, and a generation is growing up that knows little of the experiences that led to the almost universal hope that war would become obsolete. That hope now seems remoter, and it is possible that the races of mankind will, like the characters in a Greek tragedy, be driven on to disaster by forces within themselves that use reason as a weapon rather than a guide. "If you wish for peace, prepare for war" is a maxim that, universally used, leads to preparations that progressively increase, and the statesmen of many nations are even now struggling to arrest the increase. One of the first of their efforts was directed towards the exclusion of the use of poisonous gases in warfare, and various international agreements have been signed with that object. Yet there is a belief, freely expressed, that our objections to its use are as futile as were our ancestors' objections to the introduction of firearms in war, and that no nation will, when put to the test, refrain from the employment of all the means at its disposal in spite of paper agreements. Further, it is argued that gas is a more humane weapon than high explosives, inasmuch as its use against the civil population would bring greater and speedier military and political advantage with less suffering and death. The side would win that first produced uncontrollable panic among the home population of the other and, since defence against hostile aircraft is apparently an unsolved problem, and poison gas is easily manufactured almost as a secondary product of industrial chemistry, we must admit the force of the argument and realise that in our next experience of civilised warfare its bodily effects will be brought home to all, irrespective of age or sex. With these considerations as justification, the St. John Ambulance Association has published a brochure by Major F. R. Humphreys, late R.A.M.C.(T.) and Royal Air Force, on Protection of the Civil Population in Chemical Warfare, which describes in simple language the effects of the different poison gases likely to be used, with the defensive procedure to be adopted by the victims, and outlines the special duties that would fall to first-aid units. In the preface Major-General P. S. Wilkinson announces that the manual has the approval of the Chemical Warfare Research Department of the War Office and assumes that detailed organisations will be set up to deal with the work of defence. Medical men who feel the need for information will undoubtedly find the manual useful; it deals only with the material issues immediately concerned with gas attack and makes no reference to wider questions that inevitably arise in the mind of the reader. These questions are, however, frankly faced by Dr. L. P. Lockhart in the January number of the *National Review*. This writer, indeed, considers the questions settled and anticipates a war in which gas attack upon the civil population will be the decisive weapon. He declares that "the hope that the use of gas against civilians can be prohibited is . . . opposed to the whole trend and evolution of twentieth-century warfare in its relation to the economic and scientific needs of the modern State." Viscount Grey of Fallodon is quoted as saying that "it is by bringing home to each succeeding generation what the realities of modern war are, how vastly more catastrophic and destructive it is to the whole population than ever before, that we shall form a public opinion which will help to secure peace," but the argument of Dr. Lockhart, in which he is supported by Mr. J. B. S. Haldane, is that poison gas is so humane that the public can be educated to anticipate its use and "trained to realise that, with the proper measures, they have little to fear." Our possible enemies must not be expected, however, to remain ignorant of these proper measures, and this latest advance in *Schrecklichkeit* will surely go the way of all other warlike inventions. We hope that the wit and goodwill of mankind will succeed in breaking this vicious circle but, if the outlook is as bad as Dr. Lockhart thinks, then it is plainly our duty to prepare ourselves for the work we shall be called upon to do in alleviating the sufferings of the civil population in the next war. The extent of this preparation is wider than one might expect; Dr. Lockhart advocates, for example, that city, borough, and county councils should be responsible for the creation and maintenance of adequate anti-gas defence, and he presses the new and urgent need for the removal of our large hospitals from the centre of London on the ground that they may cease to function in time of war. Perhaps it is well that we should be thus reminded of the alternatives before us.

A CHANCE FOR EPILEPTIC CHILDREN.

THE epileptic boy or girl who has been excluded from school because his fits are so frequent or severe is in an unhappy position. If school is an unsuitable place for him, small homes or crowded streets are more unsuitable still. To the handicap of this disease is added the further handicap of want of education. He grows up literally without a chance in life. Medical men who come across these cases in private practice, or in the out-patient departments of hospitals, will therefore be glad to know that there is to be a further opportunity for London epileptic children to go to a school in the country, where they will receive the education of which they stand so much in need, combined with active medical supervision and treatment. The London County Council has arranged that some 80 additional places shall be made available at Lingfield Epileptic Colony, Surrey, where the instruction given resembles that associated with the ordinary public elementary school. In addition, manual training and open-air occupation are provided. The children are housed in villas and special attention is devoted to their comfort and recreative pursuits, whilst it is possible to ensure the regularity of hours so essential to successful treatment. Continuous observation, which is, of course, desirable for all patients suffering from epilepsy in its varying manifestations, is maintained by the medical superintendent, and the children are sent home as soon as their condition may be deemed to be arrested. In cases where the epilepsy persists, residence at the school is permitted up to the age of 16 years. Children between the ages of 7 and 14, resident in the County of London, are eligible for admission, and all applications should be addressed to the Education Officer, The County Hall, S.E. 1. In view of the fact that, in the past, there has been a considerable waiting-list, speedy application is

advised. The more urgent cases will receive priority but, subject to this proviso, applications will be dealt with in the order in which they are received, and every effort will be made to secure admission as early as possible. It should be noted that the provision at this school is made for educable children only.

SUPPLY OF EGGS TO HOSPITALS.

DURING the next few months the marketing of eggs will undergo a number of changes that may well give rise to fundamental reforms. The "national mark scheme," beginning on Feb. 1st, is a voluntary one, but already nearly a hundred accredited packers have promised their adherence to it. Under this scheme eggs will be graded for retailing in three classes, according to size, and only new-laid eggs will be sold under the "national mark." The scheme is designed to help British producers to secure the market in this country, and its success, of course, depends on the extent to which the producers seize the opportunity, and the purchasers support them by demanding "national mark" eggs. On March 1st there will come into operation a clause of the Agricultural Produce (Grading and Marking) Act, 1928, requiring retailers to mark all home-produced eggs that have been preserved. Later on, probably in April, an Order in Council will come into force, insisting that imported eggs shall be marked with their country of origin, and another clause of the Act will require all home-produced eggs that have been cold-stored or gas-stored to be marked before they leave the store.

These changes affect the public health very closely. Eggs are extensively used in the home and play an important part in many invalid diets; they are easily prepared, readily assimilated, and contain more nutriment than most other natural foods. But it is important that they should be fresh. Mr. James Gatecliff, in an interesting booklet [1] on the subject, goes so far as to say that the stale egg is not merely useless but actually harmful, and proceeds to criticise the supply of eggs to hospitals on the ground that insufficient care is taken to get them fresh. Egg-purchasing has, of course, a peculiar difficulty for the hospital authority, who must obtain large supplies of reliable eggs at the lowest possible rate. At present many institutions put out tenders for their egg-supply, making as the chief, or only, condition that the eggs shall weigh at least 2 oz. Many egg-distributors deplore this proviso, because the average pullet at its first laying season produces an egg which is just under 2 oz. in weight, but otherwise entirely satisfactory. They say that the hospitals could save money, without any deterioration in the quality of the eggs they receive, if they changed the 2 oz. standard. Mr. Gatecliff, however, maintains that at the present time many hospitals save money at the expense of their patients, and declares roundly that "the present methods of obtaining eggs for charitable institutions is not only a disgrace but a national scandal." He records a visit to a large relief institution in London, where he found that the so-called "new-laid" eggs were at least three weeks old. He relates that a large London hospital sent out tenders for first-grade British new-laid eggs and turned down a tender of 1*s.* 10*d.* a dozen as too expensive at a time when a number of poultry-farmers—between them supplying some 100,000 eggs a week—informed him that their lowest cut-price for really fresh eggs was 2*s.* 3*d.* per dozen. Mr. Gatecliff suggests as a remedy that firms of established reputation should be instructed by the hospital authority to purchase eggs at statutory market prices, thus abandoning the present system of commercial tendering. It might be interesting for the conscientious hospital administrator to investigate his egg-supply for, say, a week, and see what proportion of the eggs sent up to the wards could genuinely be classed as new-laid and suitable for the invalid. A simple test to determine the age of an egg is to drop it gently into 5 or 6 in. of water in a flat-bottomed vessel, 1 oz. of common salt having been added for each pint of water. A new-laid egg will fall to the bottom and lie flat on its side. An egg between 12 and 21 days old will settle at an angle, the broad end rising. As age progresses the angle increases, until the egg stands upright on its base. Later still, it will float upright, while the "electric egg" will float on its side on the surface. This test will not work with eggs preserved in lime or water-glass, but there are three useful guides to the preserved egg. First, the shell will crack from crown to base in boiling; this is specific. Secondly, the yolk is displaced, often touching the shell. Thirdly, the white is watery and has lost its firmness and elasticity.

If Mr. Gatecliff's accusation is justified it is a grave one; otherwise it calls for disproof. Dr. G. Clark Trotter, medical officer of health for Islington, who writes a preface to Mr. Gatecliff's booklet, initiated in our columns a correspondence [2] which revealed the difficulty experienced under the old regulations, both by the public in obtaining new-laid eggs and by the medical officer of health in ensuring that the eggs on sale in his area were properly described by the retailer. The new arrangement have long been desired by reputable egg-marketing firms, and they seem to meet the needs of our correspondents very adequately. Certainly no hospital ordering its eggs under the "national mark scheme" need fear Mr. Gatecliff's investigations, and it is surely not too much to ask that all hospital authorities should see that the food of their patients is at least as pure as their drugs.

PUBLIC HEALTH IN GUERNSEY.

THE Channel Islands have a deserved reputation for salubrious climate and other amenities. It is interesting to compare the conditions of public health with those of England and Wales and to note the problems which the local authorities have to face. The report for 1927 of the medical officer of health for Guernsey tells us that Guernsey has an area of about 25 square miles and a population just under 40,000. Its natural beauties are great, its soil very fertile, and the climate attractive, cooler in summer and warmer in winter than on the mainland. The average hours of sunshine over 34 years have been 1897. The water-supply from deep wells belongs to the Government and is "of exceptional purity." During 1927 Guernsey exported 24,509 tons of tomatoes, 3217 tons of flowers, 1165 tons of grapes and 2304 tons of vegetables. Presumably the islanders have plenty of these requisites for themselves. Most of the fruit is grown under glass. An additional export was 195,591 tons of granite for road-making. The milk herds are free from tuberculosis. The health statistics are good in part. Infant mortality is higher than in England and Wales and about double the New Zealand rate—75 for 1927. The neonatal rate, 46, was also high. The pre-school child rate was 24. On the other hand the maternal rate from childbirth is about half that of England or New Zealand. During the last 27 years there have been 24,593 births and 53 maternal deaths from childbirth—a rate of 2·15 per 1000 births. During the last two years one-seventh of the total births took place in the Lady Ozanne Maternity Home. There is no health visitation or effort to educate the mothers. At the end of 1927 arrangements were made for "part-time" school nurses. The tuberculosis death-rate is somewhat high. Granite quarrying is acknowledged to be an occupation predisposing to phthisis, owing to the presence of free silica in the rock, but one would not expect raising flowers and fruit under glass to be an unhealthy

ccupation. There were eight deaths from non-ulmonary tuberculosis in 1927 and four in 1926. t would be interesting if it were possible to obtain ost-mortem examination of these small numbers of eaths yearly, in order to ascertain if the absence of ne bovine bacillus confirms the claim that the cattle re free from tubercle. The respiratory death-rate as satisfactory except for the death-rate of children nder one year, which would no doubt be improved y the work of health visitors. For years mumps as absent, but was introduced by school-boys from ngland during 1927. No cases of ophthalmia eonatorum had been notified for many years, but wo cases, both ending in blindness, occurred in 927, possibly because there were no health visitors o give the needed warning. The States have built 117 ouses since 1921 and 80 were under construction uring 1927, but Dr. Bishop would like to see baths stalled in all the new houses. At present very few ouses have baths and there is an urgent need for ublic baths. Although the water-supply is constant, here is no power to compel its being laid on to existing ouses, and this lack of proper water-supply in some f the poorer parts is a great hardship and danger. s Dr. Bishop puts it—cleanliness being next to odliness—if the islanders were as well provided ith baths as they are with churches and chapels here would be no cause for complaint. The last stalment of States houses will enable the worst um to be cleared, but Dr. Bishop shows that several f the slum tenants will not willingly leave their resent surroundings.

PROFESSIONAL ETIQUETTE.

THE recently published rulings of the General ouncil of the Bar upon doubtful points of etiquette nd conduct are of interest to other professions. wo points in connexion with advertisement are pecially dealt with. A barrister inquires if there any objection to his broadcasting a short course f popular lectures on general topics of law with the sual insertion of his name and short particulars the *Radio Times*, and the description "barrister-t-law." He also asks—with a courage which will nock the older generation of barristers strictly ained in circuit discipline—whether his photograph ay appear in the B.B.C.'s quarterly "Talks and ectures." The General Council of the Bar answers at he may broadcast the lectures as given by a barrister-at-law," but that his name, address, and notograph must not appear. Thus novel wireless evelopments have raised an old issue afresh; few arristers can have had any doubt as to how the ouncil would decide. The decision is in keeping ith the long-established principle forbidding a ember of the Bar to advertise himself by articles nder his own name on legal topics in popular journals. pecialist articles in specialist publications like the *aw Quarterly Review* are, of course, on an entirely fferent footing. The second point of this nature alt with by the Bar Council's Annual Statement for 928 is the answering of legal questions by barristers newspapers. Here the Council republishes a rmer "warning notice" which it has caused to be splayed also on the screens of the Libraries and ommon Rooms of the Inns of Court during the past ar. The notice observes that the Council's atten-on has been called to the increasing practice of gal journals advising or professing to advise their bscribers on points of law arising in actual practice. mentions a recent instance where a firm of pub-shers has offered free advice on conveyancing atters to all subscribers to one of its publications. he Council has no means of knowing whether such lvice is supplied by members of the Bar, but it lieves that in some cases the advice is represented the client as being "Counsel's opinion." It affirms its former rulings and declares unequivocally at it is contrary to professional etiquette for a rrister to answer legal questions in newspapers periodicals, whether for a salary or at ordinary legal remuneration: (1) where his name is directly or indirectly disclosed or liable to be disclosed, or (2) where the questions answered have reference to concrete cases which have actually arisen or are likely to arise for practical decision. A barrister inquired if the Council would give any further guidance by defining more narrowly the reference to "a particular question likely to arise for practical decision." Not to be drawn into hypothetical cases, the Council replied that it was a matter for the discretion of the barrister himself. That final answer counts for much in these cases of doubt. If a professional man knows that certain forms of self-advertisement are illegitimate and contrary to the accepted traditions of his fellow-practitioners he can refrain from treading close to the border-line. Every profession has its members who sail close to the wind; their colleagues know them and form their own opinion. In this matter of advising on technical questions in journals the legal profession has probably had some increased demand or opportunity lately in view of the revolution in the law of conveyancing and real property which has sent back to school again many men of long experience and adequate instruction in the older law. The medical profession is here not quite in the same position as the legal. Advice upon health is a personal matter; the patient must be seen by the practitioner, whereas in many cases a barrister might be able to give an opinion—upon the interpretation of a clause, for instance, or upon the inference to be drawn from correspondence—without an interview. Moreover, questions of health are usually more urgent than questions of legal rights; a patient may be unwilling to wait a week for the printed reply. In other respects there is no great difference between the official standards of the Bar Council and the General Medical Council. In both professions there will be members, junior as well as senior, who are a law unto themselves. The standards cannot be upheld unless they are supported by the general approval of the rank and file. If they have that approval, they are entitled to the loyal obedience of all.

CHRONIC ULCERATIVE COLITIS.

DURING the last few years a good deal of interest has been shown in the subject of chronic diseases of the colon, and several important contributions to the medical literature have appeared lately. J. A. Ryle [1] has given a good summary of the clinical aspects and relationships of the visceral neurosis known as spastic constipation or spastic colon, with its allied condition muco-membranous colitis; diverticulosis of the colon has occupied the attention of meetings of many medical societies, and a full description of its clinical features, complications, and treatment appeared in this journal last year [2]; while chronic infections of the colon formed a subject of discussion at the meetings this year both of the British and American Medical Associations. The discussion at the former [3] covered the broad ground of the flora of the fæces and the relation of the bacteria found to diseases of the bowel and of the body generally. Part of the discussion turned on the possible causes of chronic ulcerative colitis and references were made to the claims of the enterococcus or fæcal diplostreptococcus as a causative agent in this complaint; these claims were regarded as non-proven. At the meeting of the American Medical Association,[4] however, strong support of these claims was brought forward by J. A. Bargen and others. In 189 cases of chronic ulcerative colitis observed at the Mayo Clinic, Bargen had isolated in pure culture a diplostreptococcus with definite morphological, cultural, and biological properties, which he has come to regard as the ætiological agent in the disease. The strains isolated were

[4] Jour. Amer. Med. Assoc., 1928, xci., 1176.

injected intravenously into 459 healthy rabbits, and in 268 rabbits reactions were observed varying from marked diarrhœa to extensive hæmorrhages and severe ulceration of the colon. Following up these observations, Bargen has attempted the specific treatment of cases of ulcerative colitis by vaccines, and more recently serum, prepared with the diplostreptococcus as antigen. He is able to report since 1924 a series of 250 cases of chronic ulcerative colitis, in which 70 per cent. were entirely free from bowel symptoms from 16 to 52 months after the beginning of treatment. This good result over a large number of cases is suggestive, and if confirmed by other workers will be a distinct advance in the treatment of the disease; but, in the discussion following Bargen's paper, the bacteriologists were not in agreement with his findings that the diplostreptococcus is so frequently associated with the disease, or the clinicians that specific vaccines and sera were so helpful. The cultures were made by smears from the surface of rectal ulcers when observed with the proctoscope, and the organism may be, therefore, only a predominant secondary infection. The diplostreptococcus, too, is found in a considerable number of healthy people, but these strains, though morphologically similar, appear to have only slight pathogenicity for animals. On culture media the organism grows either in a "smooth" colony composed mainly of diplococcal elements or short chains, or in long chains which curl up upon themselves and present a "rough" appearance. In other bacteria the "rough" and "smooth" forms show wide variations in their antigenic properties. It is possible that differences in such characters may account for discrepancies in the views of Bargen and others, and that the difficulty may be resolved by further study.

Bargen reports that at the Mayo Clinic in 1927 there were three times as many cases of chronic ulcerative colitis as in the years before 1923. Many of these must be early cases and more amenable to treatment, and it may be surmised, too, that increasing experience has developed an improvement in the non-specific therapy which is carried on side by side with vaccine and serum treatment. Careful attention to diet and building up of the strength of the patient is necessary, and bowel lavage most helpful. Surgical measures, such as appendicostomy and cæcostomy, appear to be of doubtful value. Max Einhorn has advocated treatment by flushing of the colon with the intestinal tube by the oral route, and reports three cases successfully treated.[5] A narrow tube 2½ to 3 metres in length was swallowed and fixed when the end was observed by radiographic screening to be in the cæcum. By its means 60 c.cm. of 0·5 per cent. mercurochrome or 100 c.cm. of 1 per cent. yatren solutions were instilled into the colon daily, or daily instillations of a quart of 0·05 per cent. calcium carbonate were made through the tube which was left in position and anchored by string and safety-pin to the shirt of the patient. The tube might remain in place for three weeks while daily treatment was going on before being withdrawn by the mouth.

A. F. Hurst[6] has used with excellent results over some years a polyvalent antidysenteric serum. Absence of positive findings of dysentery bacilli in these cases had led to the belief that the treatment was non-specific; but recently P. H. T. Thorlakson[7] has reported the isolation of dysentery bacilli in four out of five cases (three of Flexner group and one of Shiga type) where scrapings of the ulcer wall were taken with a sharp cutting curette. Improvement followed the use of serum prepared from the bacilli isolated.

The just estimation of the results of any method of treatment is liable to be fallacious owing to the slow evolution and relapsing character of the disease; but now that the attention of the profession is being drawn to these cases, their early recognition should improve the prognosis. The successful manageme of this complaint calls for all the skill and resourc and patience of the physician, and for whole-heart coöperation and faith on the part of the patient.

INFLUENZA IN GREAT BRITAIN.

AN anxious watch is being kept upon the inciden of influenza in this country, since it is only too like that the American epidemic will find its way acro the Atlantic. As the disease is not notifiable it by no means easy to decide whether this calamit is already upon us. Those who have studied th weekly reports of infectious disease in England an Wales (see page 156) will have noticed that th death-rate from influenza is slightly rising, but far the maximal number of deaths from this cau during a single week has not reached 100. This migh suggest that Great Britain is as yet free from th American infection, but unfortunately it must b noted that a considerable number of deaths hav been notified from Glasgow, where a sharp outbrea began about a fortnight ago. The *Manchester Guardia* which has collected information about the inciden of influenza in the North, reports that all the avai able accommodation in the municipal hospital Glasgow was taken up last week-end and that pne monia is becoming a frequent sequel of attack Some idea of the proportions of the epidemic may b gained from the fact that the fares taken on th tramways last Sunday were 30 per cent. below norma whilst the number of deaths in the city during th week ended Jan. 12th was 645, compared with 38 in the week before. Those attributed to influenz number 49, whilst bronchitis and pneumonia accounte for 73 and 118 respectively. The total figure for th week corresponds to a death-rate of 31·2 per 100 per annum. The information collected by the sam newspaper from Wigan, Bury, Derby, Northwic Oldham, Stalybridge, Heywood, Burnley, Buxto Preston, and Stockport reveals no abnormal outbrea of influenza at any of these centres. Dr. C. O. Stall brass, assistant medical officer of health for Liverpoo is quoted as saying that there is no evidence of an epidemic in that city at present, but that there ma be a good deal more of it than is suggested by th notification of four or five deaths a week. "Influenza, he adds, "is said to travel at about the same rate the mail. An outbreak of influenza is about due an the weather conditions are favourable to it, bu there are no indications that it has arrived yet. Attention is drawn by Dr. A. R. Erskine, medic officer of health for Abram, to the danger of th disease breaking out in industrial areas such as th coalfields, where a widespread epidemic may mak it necessary to engage extra nurses and instal foo kitchens. The risk of removing pneumonia patient from their homes cannot be forgotten, and in village where there is much unemployment and little money with perhaps a scarcity of food besides, a situatio may well arise which will severely tax the powers the public health services and of charitable organisatio

Dr. Fernand Widal, professor of internal patholog in the University of Paris and physician to the Cochi Hospital, has died at the age of 67. The agglutinatio reaction bearing his name is only one of many contr butions which medical science owes partly or com pletely to his labours, and in the domain of clinic medicine he was equally eminent.

RECOVERY OF EXPENSES BY A HOSPITAL.—A ca was heard at Colwyn Bay county court on Jan. 10th which the governors of Colwyn Bay and West Denbighshi Hospital sued a former patient for 4 guineas in respect maintenance. It was stated that this patient, who ha been injured in a motor accident and had been treated private at the hospital, had failed in a claim for compens tion. He did not appear and was not represented. T registrar ordered that he should pay £1 a month.

Modern Technique in Treatment.

Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXXXVIII.—THE TREATMENT OF THE BROKEN NOSE.

THE nose, being the most prominent feature of the face, is a very frequent site of injury. Its fracture is far commoner than the profession realises and, though it is rightly classified as a minor fracture, appropriate and prompt treatment becomes a matter of import when æsthetic and functional values are taken into consideration. Probably only a very small proportion of broken noses receives the best treatment and a more definite policy than that usually adopted is, in our experience, likely to be successful. A large percentage of traumatic septum deformities would never have to be submitted to difficult submucous resection if the broken nose were "set" adequately at once or within two or three weeks of the injury; various minor disabilities arising from bony displacement would not occur; while the resultant deformity—varying, objectively, from a slight bump or misalignment to a serious disfigurement and, subjectively, from a trivial annoyance to an overbearing inferiority complex—would be definitely avoided.

Diagnosis.

The diagnosis of the condition is not always an easy matter. By the time the nose is seen by a doctor there is usually so much swelling that the displacement is not obvious, and so much tenderness that it cannot be discerned by palpation. X ray examination is not always available or, when available, applicable with success. An antero-posterior view is useless except to give evidence of the extension or not of the fracture into the septum; in lateral views one side of the bony vault is superimposed on, and occludes the other. Although stereoscopic radiograms often confirm the suspicion of fracture, there are, as yet, no definite positions in use which give a clear conception of the complicated nature of the fracture. A small film placed on the side of the nose and exposed to a softened tube will nearly always suffice, however, to determine the presence or absence of fracture; such X ray evidence should be more easily obtainable, not so much from the point of view of guidance in treatment as for the purpose of safeguarding the profession and of encouraging the patient to submit to early corrective manipulation. Fig. 4 shows that good and instructive views can be taken.

In the absence of X ray evidence and in the presence of swelling, it is perhaps wise for the practitioner to allow the latter to subside sufficiently to convince himself and the patient of the amount of displacement and deformity present.

C = Fracture with displacement to the left and impaction on the left side.

1. Frontal process of maxilla. 2. Nasal bone. 3. Septum nasi.

Varieties of Fracture.

The type of displacement of the bony and cartilaginous components of the nose depends on the direction and severity of the blow and also on the shape and size of the striking surface. The smaller and sharper the striking surface, the more is the injury localised to the line of impact. Conversely, contact with a broad surface produces displacement and tends to cause impaction of the fragments.

There are three directions of the blow which may be usefully defined: (1) from the side and directed at right angles to the side of the bony arch; (2) from in front and received

directly on the prominence of the bridge; and (3) from below directed chiefly against the lower border of the septum. Combinations of these are common, the most usual being one from the front and side. When the blow causing this type of fracture is severe, the man in the street knows that the side of the nose receiving the blow is pushed in, the opposite side is pushed out, and the front of the nose is pushed back. More precisely, the *frontal processes of the maxilla* are fractured at their bases and at their junctions with the nasal and frontal bones, one being displaced inwards and the other outwards, both rotating on their fractured bases. The *nasal bones* are fractured from their several osseous unions and are carried as a whole in a direction continuing the line of the blow, rotating so as to produce, with the displaced frontal processes, the typical hollow on one side and convexity on the other. The *septum*, also, is fractured and displaced. It is bent in its upper part, following the bony framework and considerably narrowing the airway above, while in its lower part it is often dislocated from the nasal crest of the maxillæ. Actual fracture with comminution and even impaction or overlapping may occur, the latter most frequently as the result of a blow direct from the front.

The First Three Weeks.

Preliminary cocainisation is to be recommended and general anæsthesia is advisable, ideally administered by the double-tube endotracheal method of Magill. Where the latter is not available, adequate steps should be taken to prevent inhalation of blood. The skin of the face is cleaned with spirit and the nostrils are cleared of all blood and mucus collections, and painted over with spirit or other antiseptic.

The aim of the operators should be: (1) to displace both frontal processes, (2) to disimpact both nasal bones and bring them forwards, (3) to straighten the septum, and finally, (4) to push in the frontal processes and mould the whole arch with th fingers.

Walsham's forceps, right and left, are used for manipu lating the nasal bones and frontal processes. It is we

FIG. 5.

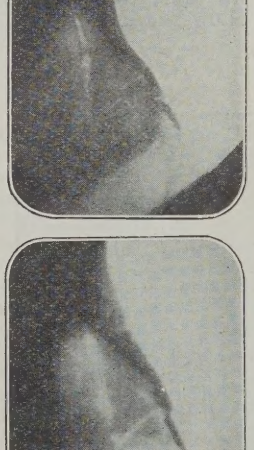
The photographs (B) were take to show flattening of the lef malar region due to a con comitant fracture in thi region; they illustrate well th deviation of the bridge line an the result of operative correction

FIG. 3.

Nasal fracture with deviation to left. Result of corrective operation 23 days after injury.

FIG. 4.



Radiograms showing several lines of fracture in nasal bone. (A, by Dr. Graham Hodgson; B, by Dr. Bertram Shires.)

to cover the outer, larger blade of these forceps with rubb tubing to prevent damage to the skin. One or both of tw quite distinct actions may be employed in using the forcep Taking the left frontal process in the fracture depicted i Fig. 1 B and C in one method, the blades having been applie the instrument is rotated by the act of supination of th wrist of the operator; in the other, the wrist remains pronate and the bent elbow is raised from the operator's side, the gri of the blades on the bone being held firm throughout.

A direct, accurately aimed blow with a mastoid mall over the upper ends of the nasal bones, the skin bein protected by gauze and the eye carefully guarded, is fr quently necessary to achieve finality in mobilisation. Suc a blow requires considerable nerve and steadiness on th part of the operator.

Walsham's septum forceps are employed for straightenir the septum, the blades being passed one on each side successive grasps and twists, varying according to the typ of displacement, are made until the whole septum is sati factorily reset in a central position. Finally, the septu forceps are inclined forwards so as to elevate the liberate nasal bones, while the fingers push in the mobilised front processes behind them (Fig. 2 B and C).

The operator should not be satisfied until he ca push the nose into an overcorrected position an until it will stay in that position without support Any result short of this indicates that disimpactio and mobilisation have not been fully carried out.

After treatment consists in applying cold compresse at first and later, in instructing the patient how t massage and manipulate the nose. The latter is c definite value during the second week, especiall when there is any tendency to slight deviation whils consolidation is taking place. Firm pressure wit the thumbs on the frontal processes should be em ployed by the patient as soon as possible after th operation. After maintaining this pressure for a shor time, the thumbs are allowed to slip forwards an upwards. It is as well to advise that this shoul be done in front of a mirror.

Complications.

The only complication of note which has bee recorded as occurring before or after operation, i the formation of a hæmatoma of the septum. W

ve not ourselves met with this complication as a quel to operation; should it occur it must be relieved mediately it is discovered. Some rare cases of psis tracking upwards through the cribriform plate e reported in the literature.

Other Varieties of Fracture.

Other varieties of fracture are treated on similar nes. Where minor displacements of the nasal nes only have occurred, it is not necessary to obilise the frontal processes or to interfere with the ptum. When the nasal bones have been much mminuted by a localised heavy blow and the ighbouring part of the septum has been damaged, ution should be used in prognosis as to restoration good contour.

Fractures with Mal-union.

After the third or fourth week consolidation has ken place and the simple operative procedure out-ned above will not be sufficient to correct deformity. all old, established fractures incisions must be ade in the lateral vestibular walls, the periosteum d skin raised from the bones, and adequate saw and isel cuts made before mobilisation can be attempted. such cases, if the septum be involved, it may crack" back into correct position when the over-ing roof has been raised and the septal forceps have en applied. Many a septum that appears to emand a submucous resection can be reset in this ay. If there has been much impaction, a competent ptum operator should be asked to coöperate in is part of the operation.

"DIPHTHERIA" IN SCHICK-NEGATIVE REACTORS.

BY R. A. O'BRIEN, C.B.E., M.D. MELB.,
C. C. OKELL, *M.C.*, M.R.C.P. LOND.,
AND
H. J. PARISH, M.D., M.R.C.P. EDIN.

(From the Wellcome Physiological Research Laboratories, Beckenham, Kent.)

IT is generally agreed that a person reacting gatively to the Schick test has a high degree of otection against diphtheria. This view is in entire nsonance with a large body of immunological facts d principles, and is confirmed by: (1) the practical sence of the disease in specially exposed groups Schick-negative persons, such as fever nurses Benson, 1928; Harries, 1926; and Kinloch, 1927); 2) the general incidence of diphtheria in Schick-sted populations; (3) the small, but critical, xperiment of Guthrie, Marshall, and Moss (1921), ho deliberately inoculated Schick-positive and chick-negative persons with virulent diphtheria acilli and were able to produce diphtheria in the chick-positive persons only*; (4) the general xperience that Schick-negative people may "carry" irulent Klebs-Löffler bacilli in their throats for long eriods without any symptoms of local or general fection.

It must, however, be realised that the degree of immunity" in human beings conferred by any racticable method is relative. It implies the resence of a defensive mechanism which must be onsidered in strict quantitative relationship to the magnitude of the attack. A Schick-negative person is provided with sufficient diphtheria antitoxin to deal with any ordinary infection, but one can conceive that it might not be sufficient if the amount of toxin produced by the invading micro-organism is appreciably greater than the normal. The second point to be remembered is that active immunity is a function that may be subject to fluctuation, and any method of estimating it (such as, for example, the Schick test) is only fully valid at the time of the test. One has to determine by experience how permanent is the state of immunity registered by a negative Schick test.

A small percentage of Schick-negative persons relapse into the Schick positive condition, and there is obviously no a priori reason why these should not be susceptible to diphtheria. Park (1926) found 90 per cent. still immune after nine years. Parish and Okell (1928) found that of 533 children who were Schick negative on the original test made one to seven years previously, 98·9 per cent. were still clearly negative, and 1·1 per cent. showed a reaction which was read as positive. A second group of 440 children who were Schick positive on the original test were rendered Schick negative by immunisation. When retested one to seven years later 5 per cent. were found to be positive. The positives in both groups numbered 28, or 2·9 per cent. of the entire series. The further observation was made that 24 of the 28 who had relapsed to the positive state were in a state of active immunity and reacted rapidly to the minute dose of toxin used in the Schick test by producing circulating antitoxin; they became Schick negative without further prophylactic treatment. These could be regarded as able to resist an attack from the diphtheria bacillus much more efficiently than they would if they had been in a state of what might be termed virginal non-immunity. Only 4 of the 28 children (0·4 per cent. of the entire series) required immunising injections of toxoid-antitoxin. Three of the four showed a marked rise of antitoxin within one to three weeks of the injection of a single 1·0 c.cm. dose, but the fourth child failed to become Schick negative within seven weeks, and her blood contained no detectable antitoxin—i.e., less than 1/2000th unit. She was therefore in a state of non-immunity indistinguishable, during the short period of observation, from the virginal state. In the case of this child one has no reason to postulate non-susceptibility to the disease.

The question arises—do attacks of diphtheria occur in Schick-negative persons corresponding with these different degrees of immunity, and if so, how commonly do they occur and how severe are they?

The purpose of the present paper is to discuss experiences on these points that have accumulated during the last six years among a Schick-tested population which, though it cannot be exactly enumerated, may be conservatively estimated as over 20,000 Schick-negative persons. During this time a considerable number of Schick-negative persons were met with who came under suspicion as suffering from diphtheria, but in the great majority of these the diagnosis of diphtheria was not confined by clinician or bacteriologist on further examination. It is well known that the diagnosis of diphtheria, as made under the ordinary conditions of medical practice, is beset with difficulties, and the criteria which may prove useful for ordinary clinical purposes are often inadequate to establish an unquestionable diagnosis. It is necessary, therefore, to decide what criteria should be satisfied before accepting as valid both the record of the Schick test and the diagnosis.

The possible fallacies connected with the Schick test are sufficiently well known and need not be discussed in detail. The material used for the test may have been inactive owing to faulty preparation, improper conditions of keeping, bacterial contamination, or contact with antitoxin—e.g., in an insufficiently washed syringe. If these fallacies are properly guarded against by manufacturer and operator they are negligible. One can almost always conclude that

* Some years ago we had the opportunity of watching an advertent experiment bearing on the same point. Toxin mounting to some 10 to 20 human lethal doses was injected ntradermally into a known Schick-negative reactor No pecific symptoms, local or general, occurred.

in a given Schick test the material was active, owing to the record of well-marked Schick-positive reactions on subjects tested at the same time. It is possible, too, that errors may be made, by injecting at a slightly deeper level than usual, but this does not seem to affect the test seriously.

If the full 0·2 c.cm. of the Schick dose is not injected an error in the Schick reading may occur, but, in our experience, as long as the greater part of the 0·2 c.cm. dose is injected the readings obtained are sufficient for practical purposes. Errors may, of course, be made in the reading, particularly where a "pseudo" element is present, but these, again, are almost non-existent when the tests are done by an expert operator and reader. Doubt may indeed sometimes arise during reading, but the true state of immunity of the patient can almost always be determined before definitely recording him as Schick negative.

If the injections are done with reasonable care, if readings are made at the end of seven days and again at 14 days (to avoid the real risk of clerical error in recording), and if strongly positive individuals are met with when the same material is used, there is little cause for doubt as to correctness of the Schick reading. If, however, a case of alleged diphtheria should be reported in a Schick-negative person, it is necessary to inquire into all these points. It is also important to take a 5 c.cm. sample of blood at the onset of the disease and before horse antitoxin serum is given. A knowledge of the state of immunity of the patient at the time of attack can be obtained by titrating the antitoxin in the blood, or the patient may be Schick tested. (The administration of antitoxin intramuscularly three to four hours after a Schick test does not prevent the Schick toxin from producing its proper reaction.)

The question of diagnosis is a difficult one owing to the mild and often atypical character of the disease when met with in Schick-negative persons. Before we accept the diagnosis in these cases: (1) there must be sore-throat with exudate, continuous or follicular; (2) virulent diphtheria bacilli must be present in throat or nose in predominating numbers; (3) alternative causes for the condition, such as hæmolytic streptococci and Vincent's organisms, must be excluded. The virulence of the bacilli associated with alleged cases of diphtheria in Schick-negative persons must be ascertained.

The records of any isolation hospital will show that patients admitted with a diagnosis of "diphtheria" on clinical grounds are by no means invariably found to be suffering from that disease. We have, thanks to Dr. Foord Caiger and his staff, had a valuable experience of the difficulties in diagnosis. In this investigation (Caiger and O'Brien, 1924) the clinical staff of a large fever hospital arranged to coöperate at every step in a joint investigation with the laboratory workers. Approximately 436 patients certified as suffering from diphtheria and admitted to the South-Western Hospital were included in the examination. In 41 per cent. the diagnosis could not be confirmed at any period during the patient's stay in the fever hospital. In 22 per cent. of cases the diagnosis made in the admission room had to be revised in the wards.

We have, however, met with or have records of a small number of cases of diphtheria in "Schick-negative" persons, 18 in all, in which there was no serious reason either to doubt the record of the Schick reading or to question the diagnosis. The data were not equally complete in all these cases, but in a few of them we are able to make a reasonable attempt at an immunological classification.

The first type of case apparently illustrates the occurrence of a mild diphtheria in persons, once Schick negative, who had relapsed into the Schick-positive state (or whose circulating antitoxin was shown to have been low by blood titration) by the time of the onset of the disease.

CASE 16.—A nurse, three months in ward with unusual number of severe cases of diphtheria; previously immunised, passed as Schick negative 19 months earlier. Titration blood at onset of attack, 1/500th unit of antitoxin per c.c (therefore now Schick positive). Discrete "membrane" on both tonsils. Sore-throat. Virulent K.L.B. isolate Temperature normal throughout. The whole attack w considered trivial and the patient recovered rapidly witho antitoxin being given.

CASE 11.—A nurse in another fever hospital; previous recorded as Schick negative after immunisation. Titratio of blood at onset of attack showed 1/100th unit per c.c Small patch of "adherent whitish exudate." Virule K.L.B. isolated. Attack very mild, temperature norm throughout; pulse throughout below 90, patient recover rapidly without administration of antitoxin.

The mildness of these two cases and their tendenc to recovery without treatment indicate that, thoug their circulating antitoxin had fallen to a low leve their active immunity allowed them to produce ant toxin rapidly, and by their own effort to cut short th disease. These two nurses evidently belonged to th group of Schick-positive but actively immune perso studied by Parish and Okell (1928).

The second type includes those in which the patie was found to be Schick negative within 48 hours the onset of the disease (or whose circulating antitoxi was shown to be relatively high by titration).

CASE 3.—Boy aged 13 years. Tested twice and know by us to be Schick negative. Reported at night with sor throat and moderate amount of membrane on both tonsil Patient bright, no malaise or fever. Through a misunde standing—fortunately for the completeness of our invest gation—no antitoxin was given. Next morning membra practically gone, thin veil of mucus present on small pa of tonsils, temperature 98·6° F., child alert and activ Remained well and released after few days' observatio No sequelæ. Virulent K.L.B. in swab. Blood on secon day of attack contained 1/20th unit of diphtheria antitox per c.cm.; a week later three units per c.cm.

The immunological story seemed fairly clear. Th diphtheria bacilli had multiplied in the throat, pr duced a slight amount of membrane, and made toxi Any toxin entering the body cells had been imm diately neutralised by the circulating antitoxin, b had stimulated the antitoxin-producing cells make antitoxin rapidly. The child, therefore, apa from slight soreness of the throat, remained quit well.

CASE 15.—In this case we were able to secure the fu data—i.e., clinical report, virulent K.L.B. in the throa and antitoxin in the blood. "Schick test on entry negativ Four months later, on a Saturday, complained of sor throat. Seen on Sunday. Oblong strip of read ly remo able diphtheria membrane upon left tonsil. Greyish-whit Temperature normal. No malaise. Slight reddening tissue adjacent to patch of membrane. Direct sme showed morphological K.L.B. Schick test repeated. Neg tive. The girl, of course, had not been given antitoxi She is physically fit. The local condition cleared qui rapidly—that is to say, within 48 hours—of its own accord. We found virulent diphtheria bacilli in a swab from th patient, and the blood contained 1/10th of a unit of antitoxi in agreement with the Schick-negative test.

CASE 18.—A child, who had been immunised and passed Schick negative by a careful observer eight months pr viously, developed a very mild but definite attack of fauci diphtheria. A Schick test was repeated 24 hours after th onset of the disease and was negative. A blood samp for titration was not obtained. An almost pure cultu of virulent diphtheria bacilli was obtained from the fauce The child was not ill except for a slight soreness of th throat. The "membrane" rapidly cleared up witho administration of antitoxin, and the patient recovered aft a trivial indisposition.

In this class of case one would have thought tha sufficient circulating antitoxin was present to preve the development of even transient "sore-throat." One may explain the development of disease as du to a temporary failure of the patient's active immunit when confronted with an overwhelming infectio All the cases were mild and, in most, antitoxin wa not considered necessary. The patient's defence apparently rapidly and successfully recovered them selves, probably by immediately producing circulatin antitoxin. An alternative explanation is that th toxin of certain strains of the diphtheria bacillus

t entirely neutralised by the usual antitoxin pared against the Park 8 strain. There is, however, no sound evidence available in favour of the ality of diphtheria toxin, and such observations those of Okell and Parish (1926), where the toxicity 819 consecutive virulent strains was proved to be utralisable with Park 8 antitoxin, are strongly posed to this explanation.

In the remaining nine cases insufficient data were ailable for complete investigation, and we are not le to include them in either of the foregoing categories. In one of them a severe attack occurred; e patient recovered without sequelæ after antitoxin atment. It is possible that this patient corresonds with the very rare class of individuals referred above who, though once Schick negative, had apsed to a state of non-immunity indistinguishable m the virginal state, and therefore could not be pected to react to the infection by producing culating antitoxin sufficiently quickly to cut short e attack.

Discussion.

The outstanding features of these cases of "diphteria" in Schick-negative persons are: (1) their rareess, (2) their mildness in the great majority of cases. e patients appear to have the power of dealing th the infection by means of their own antitoxic fences. In the majority of instances a diagnosis s not been easy. In some cases the "sore-throat" ay have been caused by streptococci, Vincent's ganisms, &c., and the diphtheria bacilli present in e throat of the carrier may have grown in the mporarily unhealthy tissues. In the cases under nsideration we came to the conclusion that the embrane was in all probability primarily caused the diphtheria bacilli present. To a similar type case Thorne has given the term "local diphtheria" 896, p. 703). This might be taken to indicate the esence of a slight amount of membrane in the roat caused by the diphtheria bacillus, with practilly no disturbance of general health and no sequelæ. sed in the clinical sense this definition would parently fit many of the cases discussed. From the int of view of pathology there may be some objection this term. We may conceive that the bacilli ay gain a lodgment in the throat, purely extraporeally, and that any specific diphtheria toxin ade, if it is absorbed locally, is so overwhelmed by e large quantity of antitoxin present in all the dy fluids and cells, that it produces no specific imulus to the immunity mechanism of the body and, erefore, no measurable alteration of antitoxin ncentration in the blood (cf., the intradermic jection of toxin in a highly immune person). But obably the usual course is, as in Case 3; here, ough no malaise occurred, the antitoxin concentraon in the blood rose sharply. Since the toxin had early penetrated the body cells, the whole process nnot be spoken of as purely local. Though no titoxin be given, the patient recovers normal alth in two or three days and suffers from no quelæ. This sequence we might agree to call mild diphtheria," and the phrase is used throughout is paper in this sense. It is of interest that W. H. ark (1926) "has never seen an undoubted clinical se of diphtheria occur in a child who had recently ad a negative Schick reaction after a test performed y an expert."

Whatever be the true nature of these cases, which e have taken to be diphtheria in persons once known have been Schick negative, they cannot be condered to detract from the value of the Schick test. hey appear as the exception which one must expect meet in nearly every biological rule. Their very arity proves that the accuracy of the Schick test is f a very high order and that, when properly perrmed, its fallacies are unimportant. The Schick st may still be held to stand alone in depenability mong the tests for susceptibility to disease in human eings.

With regard to the problem faced by the clinician hen he sees a patient said to be Schick negative, yet with signs and symptoms justifying an unhesitating diagnosis of diphtheria, the first duty is to the patient and antitoxin should certainly be given.

Conclusions.

Patients properly tested and read as Schick negative have a high immunity and contract diphtheria only in very rare instances. Only 18 cases in which the evidence could be considered convincing were met with in six years among a Schick-negative group probably exceeding 20,000. In every case but one the disease was mild and diphtherial toxæmia in the clinical sense was absent. The mildness of the disease is ascribed to the capacity of those who have been once Schick negative to respond rapidly by the production of circulating antitoxin. In a sense, therefore, diphtheria in those who have been once Schick negative is in the great majority of cases "modified diphtheria."

Wherever diphtheria is suspected in a patient considered to be Schick negative, the virulence of the diphtheria bacilli present and the antitoxin content of the patient's blood should be investigated.

Since this note was written, an interesting paper by A. V. Neale (THE LANCET, Dec. 29th, 1928, p. 1342) has appeared; some of the data lend added emphasis to several of our points.

MEDICAL USES OF RADIUM.[1]

SUMMARY OF REPORTS FROM RESEARCH CENTRES FOR 1927.

THIS publication is one of a series of special reports in which are recorded the results of research work done with the stock of radium salt distributed on loan to various institutions by the Medical Research Council and the British Empire Cancer Campaign. The summary here printed is based upon the accounts of work done in 1927 submitted by the several participating institutions.

The general scope of the present report does not differ very much from that of previous ones,[2] but there are unmistakable signs that radium is being more widely and confidently used in the various forms of malignant disease. A definite technique has been developed for the treatment of cancer in almost all regions of the body except the stomach.

Dosage.—In connexion with dosage the most striking thing which emerges from a retrospect of the reports is that the intensities of the radium foci have in very many cases gradually been reduced with a corresponding prolongation of the time of exposure.

For many years it was the practice to look upon tubes of radium containing as much as 20 or 30 mg. of element as the most generally useful, and the times of exposure were round about 24 hours. Now, while this may still hold for some sites, notably in cancer of the cervix uteri, it has been shown that growths affecting the buccal cavity are better treated by much less intense foci, such as tubes containing 1 or 2 mg. inserted for a week or more. At St. Bartholomew's Hospital a technique consisting of the use of weak sources with times of exposure of 10 or 11 days, has been evolved for the radium treatment of operable cases of cancer of the breast.

[1] Medical Research Council, Special Report Series No. 126. London: H.M. Stationery Office. 1928. Pp. 22. 1s.
[2] Special Report Series Nos. 90, 102, 112, and 116.

When this scheme of research was initiated by the Council in 1921, there was no technique for a single variety of cancer that was so surely established that it could be followed to the exclusion of others. Now this is no longer true. For instance, any woman suffering from early carcinoma of the cervix uteri can have the disease locally removed by means of a definitely planned course of radium treatment as surely as by surgical means; a man with a malignant growth of the tongue can likewise have the disease locally cured. In the latter case, even if the growth should have extended to the glands, radio-surgical methods would offer a good prospect of eradicating the disease. These statements, which are put forward in the report with evident conviction, spell progress. The radium therapy of cancer seems to be at that stage when the definite gains of the present will act as a stimulus to efforts in the future.

Cancer of the Breast.

The Middlesex Hospital records (1) surgical radium therapy, and (2) surface radium therapy.

(1) *Surgical Radium Therapy.*—The radium methods most frequently used in mammary cancer are supplementary to radical operation. At the time of the operation, radium in separate tubes containing 10–20 mg. of element are inserted in the intercostal spaces, supraclavicular fossa, and apex of axilla; they are left in position for 24 hours. Should visible recurrences occur, they are treated by a method which aims at encircling the growth with radium tubes. The report from this hospital contains an account of the treatment of nine cases of recurrence after operation, and in the majority of these cases the local growth disappeared. In one case where the immediate result was favourable recurrence took place in five months and "cancer en cuirasse" developed over the region of the recurrences.

(2) *Surface Radium Therapy.*—During the period under review 63 cases of breast cancer were treated including 6 of primary breast cancer, 21 of supraclavicular recurrence, and 34 of nodular recurrence. This surface radium therapy was practically all carried out by means of gamma ray applicators,[3] having a concentration of 7·5–10 mg. of radium element per sq. cm.

Such an applicator applied close to the skin often produces a slight erythema if the exposure lasts three to four hours, but if maintained at a distance of 6 cm. the time of exposure for the same effect would be about 24 hours. When the skin is intact, the aim has been to give the maximum radiation possible to the underlying primary tumour or recurrence, with the minimum skin damage. Skin damage and consequent infection has been followed by renewed growth in apparently satisfactory cases. This has been shown again lately in one of the first primary breast cases treated; after an interval of more than three years fissuring took place in a damaged area of skin and renewed growth followed.

The full exploration of surface therapy methods has been prevented by insufficient supplies of radium and by the lack of beds for the treatment of those out-patients for whom prolonged distance applications might be the best method of treatment.

At St. Bartholomew's Hospital the technique employed in treating primary carcinoma of the breast has been described in THE LANCET (1928, ii., 111). Since 1925 27 patients have been treated, all having been proved by histological examination to have carcinoma: 4 showed local improvement, but died of metastases; 12 were apparently cured; 1 was apparently cured, but died of intercurrent disease; and 10 were improving at the end of the year.

Cancer of the Uterus.

(1) *Cervix Uteri.*—Each year the statistical data contained in the reports from the different centres become more valuable, and it seems to us unfortunate that they are not recorded in exactly the same way at each of the individual hospitals. The classification of cases in three subdivisions—namely, operable, borderline, and inoperable—is followed by several of th centres, while others only adopt the first and las specification. It has nevertheless been possible t effect a grouping which provides a means of evaluatin in a general way the treatment which has been given

Statistical data have been obtained from seve centres—of which St. Bartholomew's, Universit College, and the Middlesex Hospitals have include a certain number of operable cases among thos treated, while Cardiff, Birmingham, Aberdeen, and th Medical Women's Federation have limited themselve to inoperable cases. A table shows that, whereas considerable proportion of inoperable cases remain aliv one or two years after radium treatment, this propor tion is much smaller when the interval is three o four years. The inference to be drawn from thi significant fact is either that the technique has s far improved that the results are really better tha with that adopted three or four years ago, or that, i a big proportion of inoperable cases of cancer of th cervix uteri treated on the lines specified, recurrence will occur inevitably within three or four years. the former alternative is correct, it will be prove within the next two years, when the data will b available. If the latter is true, then it is perhaps we to emphasise the fact that with some of the method which are now being extensively used there is strong probability of the recurrence of the disease within three or four years. In some, but apparentl few, centres the local treatment with radium is supple mented by means of X rays. It is rather remarkabl that this is not more often done, for the statistics some continental centres show that better end-result have been obtained when the local radium treatmen is supplemented by X rays or externally applie gamma rays. The Committee hope that some of th centres will help to decide the value of supplementar treatment.

As to technique, three main lines of techniqu are being followed at the centres, and during th period under review there have been very few change University College Hospital and St. Bartholomew Hospital record variations, while at the Gener Hospital, Birmingham, in seven cases radium wa supplemented by lead therapy, the preparation bein "choriotrope."

Interesting clinical information, often obtained a result of much very detailed clinical work, is give by St. Bartholomew's Hospital, the Medical Women Federation, and Cardiff, and is likely to be of wid use as this form of therapy becomes more genera Workers at St. Bartholomew's report that in mo inoperable patients there is no difficulty in getting ri of the growth in the uterus and vagina, but in spi of this, growth tends to continue in the deeper tissu —i.e., round the rectum—and causes strictures. is, however, by no means proved that all of the strictures are due to malignant growth, and it regarded as possible that in some they are caused b fibrous tissue. The Medical Women's Federatio discuss late radium reaction, symptoms appearin 6 to 12 months after irradiation. Pelvic and rect pain, tenesmus, and blood and mucus from th rectum are characteristics of this reaction. In seve cases there was deep rectal ulceration, and in tw fistulæ occurred. The undesirability of repeating th radiological treatment in these cases is stressed. the majority of cases, even when the reaction wa intense, the symptoms promptly subsided and th tissues rapidly regenerated. In some, repair was slo The pathogenesis of the condition is obscure. Invest gations are being carried out to find, if possible, th cause or the factors influencing its development. It attributed by the workers to the result of an obliter tive arteritis due to the irradiation, with a seconda infection of devitalised tissues. With one exceptio the rectal ulcers, including the two which produce fistulæ, were from one to four centimetres below th zone of the most intense irradiation. There was n evidence that the fistulæ were the direct result of t intense irradiation at these points. The screening h been increased in order to cut out more of the soft

[3] This means that the surface applicators used had filters attached which absorbed all but the gamma rays.

mma rays so that the injury to the superficial tissues ll be lessened without appreciably diminishing the stance dose.

The Cardiff report contains the following account of ses in which fistulæ formed :—

"Fistulæ of one kind or another developed in the course radium treatment in 13 cases (out of a total of 139); is is a high percentage, but again it has to be remembered w advanced the cases were and the likelihood of fistula rmation apart from radiation has to be borne in mind. om our clinical observations it cannot be accepted that in e majority of these cases the fistula was caused or even stened by radium."

Cancer of the Mouth, Nasopharynx, Larynx, and Œsophagus.

These sites of cancer have, during the last few ars, attracted much more attention than previously, id are, with the exception of growths in the sophagus, looked upon as distinctly hopeful for the ployment of radium therapy. Opinion still differs to the best way in which to treat a primary rcinoma of the tongue with glands probably infected ith growth. Whatever method is used, there is a nsensus of opinion that these growths respond very uch better when comparatively small quantities of dium are used and allowed to act for periods from -11 days, than when larger quantities are used for riods of 24 hours or less.

Mouth and Naso-pharynx.—At the Middlesex Hostal 30 cases of cancer of these parts were treated.

A scheme of irradiation is planned by making a scale odel in plasticine of the area to be treated and indicating e suggested positions of tubes by means of coloured pins, ch colour representing a certain size of tube. This is ken to the theatre and often affords the surgeon a useful ide to the proposed scheme. These models not only serve eir immediate purpose, but, when the patient is seen ter, it is possible to make a good comparison of the nditions before and after treatment.

At St. Bartholomew's Hospital 41 cases were treated, me of them by means of radium emanation in the rm of radon seeds. These seeds have the following dvantages :—

A small quantity of radon per seed is required, there is cutting of the tissues on insertion, they are easily retained id easily removed, and they can be used upon out-patients. ssible disadvantages are that the filtration is inadequate, ie reaction in mucous membranes is more severe than with edles, and the radon is rather concentrated.

The report states that there has been less success in ie treatment of growths arising in the tonsils than those in the other regions treated, and in fact there as been no case in which there has been apparent ire and even a temporarily satisfactory response is are.

Birmingham records the treatment of 29 cases. adio-necrosis, a late, troublesome, and very painful mplication in mouth cases, occurred in two of the ine cases where the primary reaction was severe. It nsists in a slow necrosis of the part of the alveolus ffected, and is due to the tubes being placed in too ose proximity to the bone. It is difficult adequately screen off the bone, but the condition can be revented by not giving too concentrated a dose near ie bone.

The Dublin report states that 48 cases have been eated by means of radon, the vast majority of them eing hopelessly inoperable. Special reference is ade to the beneficial value of normal saline solution the treatment of radium or X ray ulceration.

Larynx.—St. Bartholomew's Hospital reports upon ur cases of intrinsic malignant growth of the rynx, only one of which failed to respond favourably radium treatment. Of five cases which had transressed the boundaries of the larynx proper, only one efinitely improved; in this case the growth disppeared entirely, the patient remaining well for over wo years.

Œsophagus.—Previous reports, in common with hose from radium institutes in other parts of the orld, have contained nothing that could be looked pon as a hopeful or favourable method of treatment of alignant growths of the œsophagus and this still remains the position. The Middlesex Hospital and King's College Hospital report cases treated, the latter centre having evolved a development of technique.

Carcinoma of Rectum and Bladder.

Records of technique are supplied by St. Bartholomew's Hospital and Birmingham.

Sarcoma and Lymphosarcoma.

The attempt which is being made to correlate the therapeutic results of radium with the histological character of these growths makes little headway; this is largely due to the comparative scarcity of any pathological description of the cases treated and reported upon by the various centres. So far as can be ascertained, the only reports this year which include definite histological information about the growths treated are from the Middlesex Hospital, St. Bartholomew's Hospital, and the General Hospital, Birmingham.

There is no record included in the report of the technique used or results obtained in any region of the body at the London Hospital, St. Peter's Hospital, and the Royal Infirmary, Aberdeen, though these centres are mentioned in the introduction to the report among those who have been supplied with radium for research purposes.

MEDICINE AND THE LAW.

Practice by the Unqualified.

THE difference between the professional monopolies of the legal and medical practitioners is believed to be unfamiliar to the public at large. At Marlborough-street Police-court last week Mr. Mead fined a firm of auctioneers and estate agents for having infringed the Stamp and Finance Acts by drawing up an "instrument relating to personal estate" without being duly qualified. The document related to a lease. Mr. Mead held that it amounted to a deed and was therefore an infringement of the statutes which guard the legal profession's monopoly. He fined each defendant £5, ordering one of them to pay £10 costs to the Law Society who had instituted the proceedings. "I think it a great indulgence on the part of the Legislature," remarked the magistrate, "to allow persons who have had no legal training to prepare documents of a legal nature; people might suffer injustice as a result; it is like an unskilled person acting as a doctor."

There is no doubt some analogy, as the learned magistrate suggested, between the danger to property caused by unqualified persons posing as legal experts and the danger to health caused by unqualified persons posing as medical experts. But the analogy is incomplete. The unqualified person who undertakes the functions of a solicitor can be punished by law; the unqualified person who undertakes the functions of a doctor goes free. Which is the greater danger to the public?

Christian Scientists Censured for Neglect.

At a recent inquest at Doncaster upon the death of a young man of 20 from tuberculosis there was medical evidence that he might possibly have recovered with proper attention. In returning a verdict of "death from natural causes," the jury recommended that the parents be censured. The parents, who were Christian scientists, had not called in a doctor to their son. In administering a severe censure, the coroner said that they had been guilty of gross negligence; if the boy had been 15 years of age he would have advised that they should be committed for trial for manslaughter. Their belief in Christian science, he said, would have been no defence if a charge of manslaughter were brought against them.

The coroner's warning was well founded. It has long been the law that, where a legal duty exists (under statute or under contract) to look after

prisoners, children of tender years, apprentices, or helpless persons, it is manslaughter to cause death by neglect to provide the requisite food, care, and medicine. The statutory duty of parents is set out in Section 12 of the Children Act, which re-enacted earlier provisions to the same effect. Religious beliefs are no defence. This was established in 1899 in *Reg.* v. *Senior*, where the charge related to the death of an infant of 8 or 9 months from diarrhœa and pneumonia. The jury found on that occasion that the child's life would have been saved if medical assistance had been given. The father was one of that sect which declines to call in a doctor and prefers to rely on a literal adherence to verses 14 and 15 of the fifth chapter of the Epistle to St. James :—

> Is any among you sick ? Let him call for the elders of the church ; and let them pray over them, anointing him with oil in the name of the Lord : and the prayer of faith shall save him that is sick, and the Lord shall raise him up ; and if he have committed sins, it shall be forgiven him.

Mr. Justice Wills, who tried the case at the Central Criminal Court, drew the father's attention to the text : " They that be whole need not a physician, but they that are sick," but received the reply that those words were understood to apply to moral, not physical, sickness. The judge's careful summing up was referred to the Court of Crown Cases Reserved, where the observations of Lord Chief Justice Russell made it plain that the deliberate omission to call in medical aid, where necessary, for a child of tender years is not excused by the parent's peculiar religious tenets. A young man of 20, as in the recent case at Doncaster, is not a child or young person within the meaning of the Children Act ; in such a case, therefore, there is no statutory duty on the parent under Section 12. There may, of course, be a moral duty, and there have been judicial dicta, which suggested that the existence of a merely moral duty would support a charge for manslaughter.

Crime and Epilepsy.

Robert Williams, indicted for the murder of Julia Mangan, a young Irish girl, who was found beside him in Hyde Park last October with her throat cut, has been found guilty of murder at the Central Criminal Court at his second trial. The jury had disagreed at the earlier trial before Christmas. At both trials evidence was offered for the defence to suggest that Williams might have murdered the girl in a state of epileptic automatism. A witness, who knew the accused's family, said he had known five instances of insanity on the mother's side. Dr. Gordon Hume, of Fitzroy-square, who attended Williams for neurasthenia, said that in October he considered him abnormal but not certifiable. Dr. J. C. Woods, lecturer on mental diseases at St. George's and London Hospitals, said that Williams was sane when he saw him in December, but he had formed the opinion that at the time of the tragedy Williams was suffering from an epileptic mental attack. Questioned by Mr. Justice Swift at the first trial, Dr. Woods said that many people of high intelligence were going about their work although suffering from epilepsy ; he did not say they might commit murder to-morrow, but there were many who were subject to periods of automatism in which they were completely irresponsible. Dr. W. R. K. Watson, senior medical officer at Brixton Prison, said he had seen no signs of insanity or epilepsy in Williams. He saw nothing to show that Williams did not know the nature and quality of his act on the material date in October, but he could express no definite opinion, in view of the lapse of time between that date and his own examination of him. Williams's own story was that, while he was talking to the girl in the park, noises came into his head ; it seemed as if steam were coming out of the sides of his head, and as if a red-hot iron were being pushed in behind his eyes. He thought he saw Lon Chaney, the film actor, in a corner making faces at him. He did not remember taking a razor from his pocket or using it on the girl or on himself ; the next thing he remembered was a nurse washing his feet at the hospital. Aft sentencing the prisoner to death at the second tria Mr. Justice Humphreys told the jury that, in accor ance with usual practice, exhaustive inquiries wou be made by the Home Office into the allegation epilepsy. The Home Office had powers which neith judge nor jury possessed, for judge and jury we bound by the rules of evidence.

An Escaped Criminal Lunatic.

On the following day the same judge sentence a man to 15 months' imprisonment for hous breaking and theft of jewelry who was an undoubte epileptic. Dr. Watson said the prisoner had had tw fits in prison since Dec. 15th. There was evidenc of very gallant service by him at Zeebrugge and i other naval battles. He had an injury on the le side of the skull, and there might be a depresse fracture there, or a foreign body in the brain. D Watson did not think him insane. Since bein invalided out of the Navy the prisoner has had man convictions for larceny, false pretences, hous breaking, and receiving. He was certified as insan while serving his last sentence, but escaped fro Brentwood Mental Hospital. The judge observe that his present sentence would probably mean tha the prisoner would go to prison and then be sent t an asylum until the expiration of his previous sentenc It would be for the prison medical authorities t decide if he were certifiable or not.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Indications for Artificial Abortion.

FORTHCOMING reforms in the criminal code wi include many items of great interest to the medica profession. Under the present law medical men ar authorised to induce abortion only in cases wher pregnancy or birth endangers the life of the mothe For many years there has been a movement to allo them to do so when the financial or social condition the pregnant woman makes it practically impossibl to bring up the child properly. The Berlin Medica Chamber discussed this question at its recent meetin and there were many different opinions. Th Communist members proposed a resolution tha medical men should be allowed to perform abortio for social reasons and that the endeavour to preven conception should be encouraged instead of bein hindered. After a long and animated debate th Chamber turned down this resolution by a sma majority, but a motion that with the vital indicatio the social and eugenic indications should be give consideration was easily passed. The " eugeni indication " refers to cases of mental disease, epilepsy abuse of spirits or alkaloids, and also to conceptio after rape. It was stated in the discussion that i Berlin the number of normal births and abortions i about equal and that 50 per cent. of the abortions ar criminal. There are, of course, differences in variou classes and places ; according to the report of a grea Berlin sick club there were 750 abortions agains 150 normal births amongst its members. Th criminal abortions are largely explained by th shortage of dwellings and the difficulty of bringing u children owing to lack of money. The prejudic against unmarried mothers, leading to their dismissa by private employers as well as State authorities, als promotes abortion on a large scale.

Schneeberg Disease.

The Occupational Diseases Compensation Act o 1925 has attracted attention to the so-called Schneeber lung disease—a form of pulmonary cancer prevalent i workmen of the metal mines of Schneeberg in Saxony According to Prof. Saupe, of Dresden, the stone dus of the mines where the men are employed contains u to 0·5 per cent. of arsenic and has a radio-activity o

) Mache units, or more than twice that of the neigh-
›uring radium spa of Oberschlemma. No organic virus
hich can be held responsible for the disease has been
scovered. The workmen are permanently exposed
› the pernicious dust produced by drilling machines.
he clinical features of the disease are that they suffer
equently from chill and cough and from a discharge
›metimes containing blood. There is a marked
ieumokoniosis, and by and by they become weaker
ıd unable to work. Dullness to percussion is noted
. one or more regions of the lung, and a swelling of
ıe axillary and supraclavicular glands may be
›tected. The blood shows leucocytosis and eosino-
›ilia. Eventually the patients develop severe
yspnœa and cardiac insufficiency, and death
›llows a period of severe pain. Examination of the
›owths found in the lungs proves them to be cancerous,
ıd the remarkable statement is made that sometimes
vo primary growths are present in the same patient.
here is no doubt that the arsenic contained in the
›one dust, the large quantity of radium, and the hard
›nditions of work are responsible for the disease.
›chneeberg cancer develops rather slowly—sometimes
›ter 10–12 years' work in the mines. In the neigh-
›uring radium mines of Joachimsthal, Bohemia, a
milar disease is seen, but not in other mines either
ı Europe or elsewhere. Fortunately these mines,
hich were opened in the Middle Ages, are already little
orked, and there are now only about 100 miners left.

Glass Drain in the Pleural Cavity.

Dr. Relhef, a Bavarian country practitioner, has
›tely described an interesting case in the *Medizinische
Welt.* A labourer was seriously injured at his work
nd three weeks later developed an abscess on the
ght side of the thorax. On being opened this showed
connexion with the pleural cavity and a glass drain
›as accordingly introduced. Some days afterwards
ıe drain had disappeared, notwithstanding its
ccurate adjustment, and it was assumed that the
atient in his delirious stage had thrown it away.
lis condition went on improving and he was able to
›sume his work a few months after the accident. He
id so and experienced no pain during the subsequent
ine years. Then in 1927 he twice had hæmoptysis,
nd radiography showed the glass drain broken in the
›gion of the upper lobe of the lung. How it had been
roken was not ascertained, although it seems probable
hat this happened when the man was kicked by a
›orse some time ago. There is no other case on
›cord in which a glass drain has remained for so
›ng in the thorax without producing any symptoms.
ın operation is under consideration, but the patient
till withholds his consent as he has no pain from his
›oreign body.

Genital Derangements in Tobacco Workers.

Dr. Unbehann has recently published an account of
he health of tobacco workers under treatment at the
linic for women's diseases in Giessen University. He
ays that they are especially liable to disturbances and
rregularity of menstruation with severe pain. The
›rtility of these women, who mostly live in the rural
listricts of Hesse, is nearly that of the average
›opulation, but abortions are more than twice as
›mmon among them as among other women in the
ame part of the country. In three women smoking
›normous quantities of cigarettes where a pathological
›xamination of the ovaries could be performed the
›llicles showed a marked degeneration.

At the annual meeting of the German Red Cross it
vas reported that the Red Cross has 7363 local
›ranches and subsidiary societies with 1,300,000
›embers. The number has increased since last year
›y 78,000 members. There are 8000 trained nurses
›elonging to the society. First aid was given during
he year in about one million cases, and there is now
ıardly a place of importance in Germany without a
Red Cross institution.

The wife of a medical man was fined M.20 because
he drove her motor-car at a speed of nearly 35 miles an hour through a busy thoroughfare in Hamburg. On appeal she pleaded that on this particular occasion she was fetching her husband to a severely ill patient who had asked for an immediate visit. The court fined her only M.5, but regarded it as undesirable to endanger the life of several people in the hope of saving the life of a single individual.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Government Health Reports.

THE surgeon-general of the army, in his annual report, is satisfied with the health of the forces in 1927. The admission-rate for disease was 527 per 1000 ; for external causes 128. A slightly increasing rate for traumatism is attributed to more general participation in athletics and to the increasing use of motor vehicles. An increase in the annual death-rate is attributed to the occurrence of 90 cases of cerebro-spinal meningitis. The morbidity list is headed by bronchitis, tonsillitis, and gonorrhœa ; the leading cause of death was suicide, whilst the most common reasons for discharge among enlisted men were dementia præcox, constitutional psychopathic state, and mental deficiency. The director of the Veterans' Bureau reports tuberculosis as the chief cause of death, 1753 deaths out of a total of 3831 in veterans' hospitals being caused by pulmonary tuberculosis. Of the 25,899 patients remaining under treatment more than half are in hospital on account of neuro-psychiatric disability. The majority of admissions to veterans' hospitals at the present time are for disabilities unrelated to war service.

In his report for the public health service Surgeon-General Cumming states that health conditions throughout the world were generally favourable during the fiscal year 1928. Only two cases of bubonic plague were reported in North America, both contracted from infected ground squirrels in California. For the calendar year 1927 the United States recorded 34,000 cases of small-pox, a total exceeded by only one other country—namely, India. In the summer of 1927 there was a widespread outbreak of infantile paralysis. Twenty-three States reported between them 73 deaths from rabies in the fiscal year 1928. Tularæmia has now been recognised in at least 31 States and in the district of Columbia. More than 200 cases of Rocky Mountain spotted fever were reported from nine States, and the surgeon-general expresses the opinion that many more cases escaped report. A large programme of research was carried through by the Hygienic Laboratory, including research in tularæmia, undulant fever, typhus fever, and small-pox vaccination, and the standardisation of scarlet fever antitoxin. The surgeon-general asks for increased facilities for the Hygienic Laboratory and for coördination of the public health activities of the Government. A Bill to establish a National Institute of Health was introduced on Dec. 11th to the House of Representatives and referred to the Committee on Inter-State and Foreign Commerce which, under the Constitution, is the committee most nearly suited to deal with public health. This Bill not only provides for the enlargement and improved equipment of the Hygienic Laboratory, but also authorises an appropriation of a million dollars for the foundation of a new research institute. Gifts are to be invited from the American people, and the income from such gifts may be used for the establishment of research Fellowships.

Health of Pre-school Children.

The National Congress of Parents and Teachers is a powerful organisation with 20,000 units representing every economic plane. In the last three years they have sponsored a movement to ensure that the children entering school each autumn shall do so without physical handicaps. A "summer round-up"

is organised during the long summer holiday; the youngsters undergo a medical examination, and every effort is made to have the "defects" corrected. During 1927, 13,768 children were examined in this way, and the movement is apparently still growing fast. The final object is continuous medical supervision of the children from birth to school age.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 5TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 188 (last week 131); scarlet fever, 2284; diphtheria, 1333; enteric fever, 30; pneumonia, 1921; puerperal fever, 44; puerperal pyrexia, 123; cerebro-spinal fever, 8; acute poliomyelitis, 7; encephalitis lethargica, 25; continued fever, 1; dysentery, 12; ophthalmia neonatorum, 107. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 16 counties: London, 14 (Lambeth 13, St. Pancras 1); Chester, 6; Derby, 27; Durham, 24 (Jarrow 12); Essex, 7 (West Ham); Huntingdon, 3; Lancaster, 9; Leicester, 11 (county borough); Northampton, 4 (county borough); Northumberland, 20 (Tynemouth); Nottingham, 5 (Worksop); Soke of Peterborough, 3; Stafford, 4; Yorks, West Riding, 20 (Halifax 8); Glamorgan, 22 (Merthyr Tydfil 10); Monmouth, 9.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Jan. 8th–9th was as follows: Small-pox, 32 (under treatment); scarlet fever, 2075; diphtheria, 2173; enteric fever, 17; measles, 39; whooping-cough, 565; puerperal fever, 22 (plus 9 babies); encephalitis lethargica, 74; poliomyelitis, 4; other diseases, 26. At St. Margaret's Hospital there were 13 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there were no deaths from small-pox or enteric fever, 30 (2) from measles, 13 (4) from scarlet fever, 69 (22) from whooping-cough, 48 (5) from diphtheria, 60 (14) from diarrhœa and enteritis under two years, and 99 (18) from influenza. The figures in parentheses are those for London itself. The numbers of deaths from influenza during the previous seven weeks were 72, 49, 56, 60, 61, 69, and 83 respectively.

Liverpool reported 8 deaths from measles and Hull reported 5. Three deaths from scarlet fever occurred at Leeds, whilst whooping-cough caused 8 at Liverpool, and 5 each at Salford and South Shields. At Croydon there were 4 deaths from diphtheria, and at East Ham and Rhondda there were 3. Eight deaths from diarrhœa were recorded at Manchester, 6 at Liverpool, and 5 at Salford. Outside London the largest number of deaths from influenza was at Bristol and Liverpool (4 deaths each), whilst Plymouth Bury, Manchester, and Sheffield each reported 3. (Thirteen deaths from influenza occurred in Glasgow).

The number of stillbirths registered during the week was 258 (corresponding to a rate of 34 per 1000 total births), including 46 in London.

The Services.

ROYAL NAVAL VOLUNTEER RESERVE.

W. A. Sewell to be Hon. Surg. Comdr.

Proby. Surg. Lts. G. A. Mason and C. C. Ungley to be Surg. Lts.

INDIAN MEDICAL SERVICE.

Lt. W. J. A. Coldstream to be Capt.

Temp. Capt. Chandiram Ghurbamal Malkani relinquishes his temp. commn.

COLONIAL MEDICAL SERVICES.

Mr. A. R. Wellington (chief health officer, Federated Malay States) to be Director of Medical and Sanitary Services, Hong-Kong, and Mr. K. C. Yeo Assistant Medical Officer of Health. Mr. R. L. Cheverton, District Medical Officer (Cyprus); Lieut. S. P. Wilson, Medical Officer of Health (Gold Coast); and Mr. A. H. Lowther, Medical Officer (Straits Settlements).

"Audi alteram partem."

THE TREATMENT OF EARLY BREAST CANCER.

To the Editor of THE LANCET.

SIR,—Various articles which have appeared in the last two issues of THE LANCET upon the treatment of carcinoma of the breast indicate that we have reached a critical phase in the evolution of this branch of surgery. For many years the treatment has seemed to be standardised in the form of a severe and mutilating operation which has been based on the work of Halsted and Sampson Handley. Your leading article of Jan. 12th characterises this standardisation as having been effected "at a very high level of efficiency." The technical efficiency of many surgeons has no doubt reached a very high level, but if the term "efficiency" is taken to include the end-results then the justice of your statement may be doubted. Private patients are apt to seek surgical treatment at a comparatively early stage of the disease, and the proportion of five-year survivals is admittedly fairly high. But no surgeon who has carefully followed a long series of hospital patients through the five years following operation is likely to plume himself upon the "efficiency" of his work. This healthy discontent is reflected in the contributions made by Mr. Sampson Handley and Mr. Duncan Fitzwilliams, whose opinions will command the greatest respect. On the one hand, Mr. Handley predicts "fresh triumphs" for radiology conducted on a scientific basis; on the other, Mr. Fitzwilliams seeks to escape from the mutilating operation of Halsted which has been imposed upon surgeons as a routine, and states his belief that a smaller operation is often equally good in its results. Your leading article expresses an impatience with both these views, and I should like to register my protest against the rather conservative tendency which your remarks seem to betray. It is my belief that "the whole paraphernalia of scalpels, clamps, and ligatures appertaining to a cutting operation" is indeed to be largely superseded before many years are past. The grounds of this belief will be found in the statement which I made at the International Cancer Conference last July, and in the fuller account of radium treatment carried out at St. Bartholomew's Hospital which was published in your issue of July 21st. The word "cure" in relation to any form of treatment of carcinoma of the breast can only be used with the greatest caution, but it does appear to me to be now much more nearly an established fact than a pious hope, that better results can be obtained by radiotherapy in breast carcinoma late or early, than by operation. The local operation advocated by Mr. Fitzwilliams may sometimes be called for after radium has been applied; but it seems to me to be unlikely that I shall myself ever again perform the radical operation. This position has only been reached after a careful study during five years of the results obtained in 50 patients. It rests, I believe, upon a sound basis, and is largely shared by the surgeons of the Surgical Unit with whom I have been closely associated at St. Bartholomew's.

Mr. Sampson Handley emphasises the necessity for irradiating the area surrounding the growth as well as the growth itself. This principle I have long recognised, and I have applied radium mainly to the deep surface of the tumour, its periphery, and the tissues surrounding it, as well as to all accessible areas of lymphatic drainage. The results have been remarkable, and previous experience of large numbers of operated cases has convinced me that equally good results could not possibly have been obtained by operation in the same series of patients.

A doubt might be raised by the note published by Dr. H. Chambers and Prof. Russ in your last issue recording the production of a long latent period in the

rowth of tumour cells by irradiation. The only lear inference, however, to be made is that the noculated cells in their experiments had not received *lethal* dose of X rays, such as is aimed at in the xposure to radium of a week or more which I have iven. It seems unlikely that mere latency has been roduced; for the complete clinical disappearance f a tumour has been repeatedly demonstrated, and n few instances the absence of carcinoma cells in a esidual mass of fibrous tissue has been histologically roved.

Further justification of my contention can only be btained by the passage of time. Meanwhile I believe hat the surgical profession in general will do well to econsider the position from this point of view.

I am, Sir, yours faithfully,

GEOFFREY KEYNES.

St. Bartholomew's Hospital, Jan. 14th, 1929.

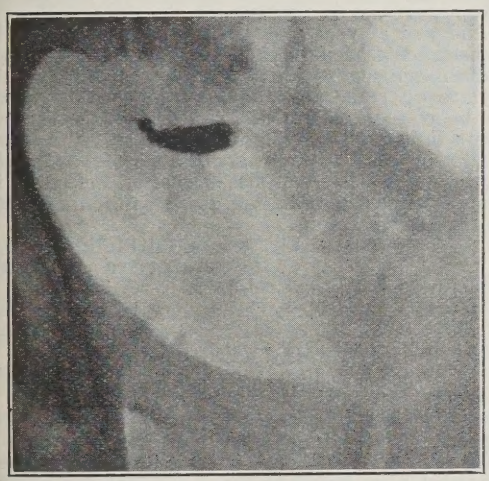
SHOT IN THE VERMIFORM APPENDIX.

To the Editor of THE LANCET.

SIR,—The interesting paper by Prof. John Fraser pon his case of Shot in the Vermiform Appendix, nd the letter from Prof. A. H. Burgess in your issue f Dec. 8th last, prompt me to record the following:—

A well-nourished man, aged 49, was sent to me in November, 1927, for radiological examination of the rinary tract, a provisional clinical diagnosis of stone in the ight ureter having been made. The examination revealed he presence of a dense elongated shadow in the right side f the pelvis. From screen examination and radiography in he recumbent position (Fig. 1) it was impossible to decide

FIG. 1.



Radiogram with patient prone.

definitely whether the shadow was produced by a stone in the lowermost part of the right ureter or by shot in the appendix. This difficulty was overcome by taking a radiogram with the patient in the upright position when it became evident that there were several pellets in the appendix (Fig. 2). On its removal, the appendix was forwarded to me by the surgeon responsible, and I was able to radiograph and otherwise examine it intact. It contained 22 pellets. Several of the pellets were incrusted with salts and were faceted so as to resemble small gall-stones in appearance; their true nature was only apparent on section. The mucous membrane of the appendix was atrophied and studded with several small discrete papillomata.

The interesting point in this case is that the patient had not recently partaken of game; indeed, he could not recollect doing so since he was a boy. It is reasonable to suppose, therefore, that the shot had been in the appendix for a considerable time; and this is borne out by the incrustation of the pellets and by the atrophy of the appendicular mucous membrane. The attacks of colic appear to have been due to attempts made by the appendix to expel the pellets en masse. The presence of the papillomata is also interesting. If I am correct in believing that the papillomata were formed as the result of irritation of the mucosa, is it not possible that they might have eventually assumed malignant characteristics?

In my experience it has not been an infrequent occurrence to find evidence of shot in the appendix

FIG. 2.

Radiogram with patient upright.

upon an abdominal radiological examination. I agree with Prof. Burgess that, in the majority of cases, the shot are probably passed by natural means; and it is questionable whether, when they are found, the appendix should be removed unless there are signs pointing to disease of that organ. This case shows, however, that shot, when present in large numbers, may become impacted in the appendix and that there is danger, in such an event, of perforation and, possibly, of malignant changes supervening.

I am, Sir, yours faithfully,

Leeds, Jan. 1st, 1929. W. H. ROWDEN.

PITFALLS IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—In to-day's issue of THE LANCET Dr. Vere Pearson mentions some of the traps that occur in the diagnosis of pulmonary tuberculosis. One of these is the question of hæmoptysis. A recent experience will illustrate the point. F., aged 50, had suffered from cough and "weak" chest for many years, and was regarded as phthisical because she had had repeated attacks of hæmoptysis. When she was seen in the spring of 1928 there was very little expectoration. Repeated examinations failed to reveal tubercle bacilli, and careful questioning showed that her "chest" attacks always commenced as a cold in the head. Investigation of her throat and nasal sinuses for a source of infection proved negative. A few days ago I was asked to see this patient, who lives in the country, with her doctor, because of a recurrence of severe hæmoptysis. She had had four attacks in the previous three days, and one was in progress on my arrival. Pulse-rate, 140; blood pressure, systolic, 160; diastolic, 100. Thinking that this would be an abnormally high pressure for her, if the condition was due to active tuberculosis, I inquired if there had been any premonitory symptoms some days before. I learned that round about Christmas she had felt poorly and could not eat. Examination of chest (brief, owing to her hæmoptysis) did not reveal much of a definite

nature, but on examining the abdomen, by palpation, I found that she was tender over the appendix and gall-bladder pyloric region. On testing a sample of the urine, it revealed acetone +++, bile +, albumin +, and what I call "leucin" bodies (? lipoid). This metabolic disturbance as a cause of hæmorrhages in various areas does not seem to have received the attention it deserves. During the past four months I have had several cases of severe epistaxis (two very severe), menorrhagia, severe hæmaturia in an old-standing pulmonary tuberculosis case during an acute allergic state, and others.

An interesting point appears in some of these cases. One of the epistaxis cases occurred after a slight operation done on the septum a fortnight before, and which had been soundly healed, and the patient returned home. Two of the menorrhagia cases had occurred in women who had been confined one or two months before, and where the lochia had been absent for weeks. It would seem as if, in those cases, there was a *locus minoris resistantiae* which decided where the hæmorrhage was to take place.

I am, Sir, yours faithfully,

R. CHALMERS, M.D., F.R.C.S. Edin.

Darlington, Jan. 12th, 1929.

THE TREATMENT OF HÆMORRHOIDS BY INJECTION.

To the Editor of THE LANCET.

SIR,—Mr. Arthur Morley's letter in your issue of Jan. 12th raises three points of interest to which, perhaps, you will be good enough to allow me to reply.

1. The question of sloughing following the injection of quinine urea hydrochloride, though a contingency which may be met with when any caustic solution is employed, is not one to which, in my opinion, undue importance need be attached. Quinine urea hydrochloride in a 5 per cent. solution is undoubtedly caustic; if it were not, its injection would not produce the reactionary fibrosis upon which the success of the treatment depends. Among the many reports of its uses is one dealing with the application of a 50 per cent. solution, applied by a spray or brush, in tonsillitis and in laryngeal tuberculosis; and though, admittedly, the conditions of submucous injection and external application are very different, one may assume that if a 5 per cent. solution is unduly caustic a solution of ten times that strength would be dangerously so. Bensaude admits that sloughing may occur, but says that the occurrence can be avoided if (*a*) one never injects an external pile or a prolapsed internal pile without first reducing it, and (*b*) if one makes one's injection as high up the rectum as possible, not in the pile mass but above it, and is careful to make the injection deeply into the submucous tissue. So far I have only had one case where sloughing occurred.

This was a lady who, four years ago, was operated on for an anal fissure and, at the same time, had had her piles dealt with surgically. When I first saw her she was suffering from marked internal piles accompanied by much hæmorrhage. A bar of fibrous tissue indicated the spot where the operation for the fissure had been performed, and at the proximal end of this bar was a freely bleeding internal pile. An injection made here was followed in three days by a sense of discomfort and fullness in the rectum. On examination a slough the size of a sixpenny-piece was visible. Further treatment was deferred for 15 days, at the end of which time the slough had separated; and, except for the three days' discomfort, the patient was no worse for the experience.

In this case the injection was made directly into the pile mass, and this fact, combined with the extensive fibrosis already present, may account for the necrosis.

2. Mr. Morley mentions that this method has been used by Dr. Tirrell and Dr. Chittenden Hill in the United States of America; but it should, I think, be made clear that both these proctologists advocate the introduction of the solution directly into the pile mass. This, at any rate, is the method explained in the last edition of Dr. Hill's book, but this book was published in 1926, and Mr. Morley may have been in communication with the author since that date. When in New York this summer I made various inquiries at the hospitals I visited, and I agree with Mr. Morley that the common practice is still the injection of carbolic oil. In my judgment, this state of affairs existed because the submucous injection by Bensaude's method was not then known. I pursued my inquiries only in New York; but no surgeon that I met was practising the method, and only one had any knowledge of it.

3. The relative value of the two antiseptics, carbolic in oil and quinine urea hydrochloride, is one on which an authoritative bacteriological opinion would be welcomed. In the absence of definite data I feel justified in questioning Mr. Morley's statement in regard to the comparative antiseptic powers of the two solutions. In a reference in Martindale (K. Taylor, li., 17, 294, 306) it is stated that quinine hydrochloride showed its greatest activity against the gas bacillus, was fairly active against the streptococcus, but little against the staphylococcus; and that the best antiseptic against the gas organism seemed to be quinine urea hydrochloride. The belief that quinine and its salts are powerful antiseptics is widely held, and if this is so one of the minor objections against the use of quinine urea hydrochloride must disappear. Mr. Morley further states in his letter that the carbolic oil solution "has the great advantage of being a powerful antiseptic and of being almost 'fool-proof' from that point of view." Is this so? Sir Lauder Brunton has said: "A solution of carbolic acid in oil is frequently used to lubricate and disinfect catheters, but Koch's experiments show that such a solution has no antiseptic power. . . ."

In the past 50 years a great many different solutions have been advocated for the treatment of this universal and distressing complaint. Amongst others, alcohol, salicylate of soda, quinine, and solutions of phenol have been recommended. Undeniably, carbolic in oil now holds the field, and in the skilful hands of Mr. Morley and others is undeniably efficacious. My opinion is that quinine urea hydrochloride is a better instrument, and time alone will show whether or not I am mistaken.

I am, Sir, yours faithfully,

CHRISTOPHER HOWARD.

Sloane-street, S.W., Jan. 14th, 1929.

ASTHMA RESEARCH.

To the Editor of THE LANCET.

SIR,—It seems to me doubtful whether the publicity campaign proclaiming that there is no cure for asthma is the best way to attract subscribers to the appeal now being issued for funds for research. In the past those unfortunate people, the asthmatics, have been treated as neurotics, and their symptoms stigmatised as nervous manifestations, and they were told they were incurable. While it must be admitted that we are painfully ignorant of the full biochemical phenomena taking place in this complaint, certain procedures have been discovered in recent years which have led to such an amelioration of symptoms as many patients are satisfied to call a cure.

Instead of reiterating the ancient parrot-cry that there is no cure for asthma, we can now encourage the asthmatic by telling him of the great advances made in treatment, and that, with few exceptions, there is hope for all. The following methods of outstanding value have each cured scores of cases: The régime of diet and exercise advocated by Dr. John Adam; the intravenous injection of peptone of Dr. Auld; the mixed coliform or entero-antigens of Prof. Danysz; the radiation of the chest of Mr. Gilbert Scott; the use of tuberculin and other work of Prof. Storm van Leeuwen; and last, but not least,

ıe dermal reactions as elaborated by Meltzer and :her American workers. Given a knowledge of the arious types of asthma, there is only one that is at esent incurable, though even that type may be elped.

Naturally, I am entirely in favour of all research hich may throw light on the problems of asthma, ut I consider the public will be more ready to ıbscribe to a venture that has paid a dividend ıd can promise more than to one which advertises s insolvency, especially when as I, for one, believe ıe latter assertion to be untrue.

I am, Sir, yours faithfully,

London, W., Jan. 12th, 1929. FRANK COKE.

MEDICAL FOUNDATIONS.

To the Editor of THE LANCET.

SIR,—In your last issue attention was directed to vo most excellent Medical Charities—namely, the oyal Medical Benevolent Fund and Epsom College. ay I bring to the notice of your readers a third, ıe Society for Relief of Widows and Orphans of edical Men, which is older than either of the two ıentioned above, having been founded in 1788 and ıcorporated by Royal Charter in 1864. The objects this Society are to help the necessitous widows ıd orphans of its deceased members, and the income the Society enables it to make substantial grants early to those in need. Membership is open to ıy registered medical practitioner who at the me of his election is resident within a 20-mile ıdius of Charing Cross; the privileges of membership re retained should a member remove outside the rea. The annual subscription is very small—2 2*s.*, £3 3*s.*, and £4 4*s.*, according to the age of the andidate.

Should any medical man, who resides within the rea, be desirous of joining the Society, I shall be very leased to send him full particulars.

I am, Sir, yours faithfully,

EDWARD J. BLACKETT, Secretary.

11, Chandos-street, Cavendish-square, W.1,
Jan 10th, 1929.

ACTINOMYCOSIS OF THE APPENDIX.

To the Editor of THE LANCET.

SIR,—I venture to question the accuracy of the iagnosis in the case reported by Dr. F. M. G. Sinclair nd Dr. S. C. Dyke in to-day's issue of THE LANCET s Actinomycosis of the Appendix. In so doing I ill not stress the pathological findings, which are otoriously difficult of interpretation in these cases nless the typical granules are found in the pus at ıme stage of the disease. I intend to confine myself ı the clinical aspect of the account.

In whatever part of the body actinomycosis may e found the pathological changes follow a very efinite series of stages. The first reaction is the ırmation of a dense, tumour-like mass which is he result of a connective tissue proliferation. Later, t various points in this mass, softening takes place ith a discharge of pus in which the characteristic ranules may be found. In my experience careful earch over a period will, sooner or later, be rewarded ı cases of true actinomycosis. In my own cases, nd in those recorded in the literature, the disease as always attacked the retroperitoneal tissues of he right iliac fossa or the muscular layers of the nterior abdominal wall. In no case within my nowledge has an infection of the peritoneal cavity ccurred at the early stage of two weeks after the ppendicectomy. It is a well-known fact that the eritoneum is extraordinarily resistant to this form of nfection and only falls to it in the final stages of the isease, when an abscess in the liver has ruptured nto the general peritoneal cavity. In my opinion he absence of any tumour-like formation, the resence of pus in large quantities within a fortnight of the original operation, and the rapid breaking-down of the wound, with exposure of the intestines, are points which negative the diagnosis of actinomycosis. On the other hand, the whole clinical history from beginning to end is typical of an ordinary pelvic abscess secondary to an acute appendix.

I have been interested in the subject of actinomycosis following acute appendicitis for some time and, in my experience, the finding of a Gram-positive streptothrix-like structure in pus from cases of acute appendicitis is not uncommon, but it is not sufficient evidence to justify a diagnosis of actinomycosis. When, in addition, the whole clinical picture is so unlike that usually found in this type of infection, then I fail to find any grounds upon which such a diagnosis can be suggested, much less maintained. The treatment of abdominal actinomycosis is fraught with so much difficulty and anxiety that I feel the diagnosis must be very certain before cases are reported as such, especially when the account contains even an implied suggestion of benefit from some form of specific treatment.

I am, Sir, yours faithfully,

R. ST. LEGER BROCKMAN.

Sheffield, Jan. 12th, 1929.

THE HEALTH OF THE YOUNG WORKER.

To the Editor of THE LANCET.

SIR,—The leading article in your issue of Jan. 12th, in which you draw attention to the gaps in the provision of medical attention for the young worker, prompts me to describe a scheme which has been for many years in force in a community of workers and their dependents. I refer to the Medical Fund of the Great Western Railway at Swindon, to which I am consulting pathologist.

The "benefits" provide for the care of an industrial population from birth to death, and comprise on the consultant staff a physician, surgeon, pathologist, and radiologist, with ten whole-time medical officers and a large (and very fully engaged) dental staff. Facilities are also provided for the customary special departments. The service is given in a hospital, a large out-patient department, and by domiciliary visits. For those who come under the National Health Insurance Act, the contracting out is arranged under the clause whereby the employee is allowed to make his "own arrangements" for medical attendance. For a few pence per week the insured person can secure for his wife, children of all ages, and other dependents all the benefits of the fund, which, incidentally, is in a very sound financial position.

It would seem that in this scheme there are not only no gaps, but the service is far more extensive than that provided under the Education and National Health Insurance Acts. Moreover, there is no official control of prescribing, or of the quality or quantity of the drugs supplied. It has also another advantage—namely, that by careful medical records it is possible to do a good deal of preventive work, and as the importance of this has been inculcated in the patients of the clinic by the medical staff, it is well recognised by members of the fund, so that, in practice, advice is sought not only for obvious disease, but for cases of indefinite illness. Another point that appeals very much to a clinical pathologist is the opportunity for research and also for consultation with one's colleagues at the bedside which is afforded. I have myself, for instance, found it possible to obtain a large amount of clinical material for almost every variety of anæmia and for obscure types of systemic infection.

It is true that we are dealing with a community which can be fairly easily served, but I suggest that a public health administration exists, not to create, but to diminish "official" difficulties and that it should not be impossible to provide continuous and effective medical treatment without "gaps" both in age and in facilities for specialist services, which exist in the

present system to which your article so aptly draws attention. I would add that the Swindon Clinic is in no sense a State medical service; it is, in fact, administered by a committee elected by the contributors to the fund, membership of which, incidentally, is not compulsory.

The advantages of eliminating the approved society in deciding how little benefit additional to the bare provisions of the Insurance Act shall be accorded to the worker, and of the continuous medical supervision from birth of the prospective worker without charity or interference by committees whose efforts may be actuated rather by emotions than by knowledge, seem to me to be inestimable. The keynote of the scheme, as it seems to me, is direct service of the worker and his dependents by a medical staff, who are independent of approved societies and State interference, and who can provide a "team" investigation and treatment of any given patient from start to finish. I imagine that this is financially possible only by eliminating administrative expenses, which have been found in practice to be quite unnecessary, but which must necessarily bulk large in any scheme administered by officials paid out of public funds.

I am, Sir, yours faithfully,

A. KNYVETT GORDON, M.B. Camb.

Bedford-square, W.C., Jan. 15th, 1929.

HISTORY REPEATS ITSELF.

To the Editor of THE LANCET.

SIR,—In Matthew Paris's "English History," Bohn Series, vol. iii., under the year 1256, occurs the following statement which bears a remarkable similarity to recent occurrences in Holborn. "About the same time, as some workmen were digging out the bed of an aqueduct at London, to clear the bed of mud (for the water had ceased to flow) a sudden explosion burst forth from the ground accompanied by a flame similar to the fire of hell, which in the twinkling of an eye suffocated several of the workmen, killing one of them on the spot, and so burning, maiming, and disfiguring others that they were entirely useless to themselves ever afterwards. There were some who said that this explosion occurred as by a miracle, because these men were engaged in servile work at an improper hour in the evening."

I am, Sir, yours faithfully,

London, Jan. 11th, 1929. R. R. JAMES.

PLEURAL PUNCTURE.

To the Editor of THE LANCET.

SIR,—As a university examiner in medicine during the last two years, I have been surprised by the fact that no single candidate to whom I have shown Potain's aspiration set has been able to assemble this apparatus; many candidates, indeed, have declared that they have never seen it before, and have no idea for what it is used. On comparing notes with other examiners, I find that their experience coincides with my own. It would appear that it has become the accepted practice to aspirate the pleural space by means of a 10 c.cm. syringe and needle. If this is really the case, I suggest that all teachers of medicine should ask themselves whether it is in the best interest of the patient that, under any circumstances, his chest should be aspirated in so perfunctory a manner. In my opinion there is only one thing to be said in favour of the syringe and needle method—it saves a certain amount of trouble. I am convinced that many empyemata go undiagnosed, sometimes till they are beyond surgical treatment, because they have been sought for in vain by the syringe and needle, whereas they would have been discovered in time had a wide-bore trocar and cannula been employed. The lumen of the needle used with a syringe is easily blocked by the thick layer of lymph which often lines an empyema cavity; moreover, the pus of the empyema may be so thick as to be difficult to aspirate through any but a wide-bore needle. If sufficient care is taken over the preliminary local anæsthesia, aspiration should be a painless operation, even when the larges cannula is employed, and it is possible, using the blun trocar, once the pleura has been penetrated, t explore the pleura with safety in various direction through one skin puncture, a manœuvre which i quite out of the question with a 10 c.cm. syringe an needle. Finally, if fluid is encountered, it is difficul to evacuate this satisfactorily by means of a syring and needle. With the Potain, or some simila apparatus, an empyema may be partially or com pletely evacuated before drainage is performed and this I believe to be sound treatment, sometime life-saving. I must apologise for occupying you space by a recital of rudimentary principles in th technique of pleural aspiration, but even if thes principles are accepted they are apparently no taught. I am, Sir, yours faithfully,

London, W., Jan. 15th, 1929. MAURICE A. CASSIDY.

THE FUTURE OF GENERAL PRACTICE.

To the Editor of THE LANCET.

SIR,—I read with great interest the leading articl on this subject in your issue of Jan. 5th. Th problem that is actually arising in general practic is the outcome of the assiduous efforts of reformer of the social system to cater for the health of th public. These persons feel that a State-administere medical service will provide for these needs. In th impoverished circumstances of the community b exploiting the doctor some attempt can be made t ensure an abundance of medical attention. Th channels through which the work is being conducte are the public health services. Originally thes departments confined themselves to the care of th public as a whole. The drainage and water-suppl was looked after. Infectious cases were followed u and isolated, not with a view to dealing with th stricken individual, but to prevent him being menace to others. The next step was in the directio of dealing with the tuberculous. A certain measur of treatment had to be provided in the attempt t stamp out the disease and prevent disseminatio This could still be considered a prophylactic publi health measure, the treatment of the individual bein justified by the fact that in curing him infection wa being checked. On the other hand, it was a com mencing incursion into the field of the practitioner medicine. The individuals of a borough paid the rates and contributed to these schemes so tha measures could be carried out because they wer prophylactic to the community as a whole.

Contrast these measures with present-day chil welfare activities, where treatment, masqueradin in the guise of prophylaxis, is given at baby clinic Is it any longer a public health service or a individual attention service, when publicly paid med cal officers have to decide whether a baby has gaine a requisite number of ounces each week, or is in th incipient stages of rickets. This is a definite attemp at State control in a certain branch of medicin and the same tendency is manifesting itself i obstetrics. If honesty was the energiser of thes schemes for prophylaxis, how is it that the firs principle of immunity, the establishment of a natur resistance by a sufficiency of food, is so easily ove looked?

Before fault is found with the system of gener practice as now conducted, measures should be taken t enhance the practitioner's clinical skill and his clinic material should not be perpetually encroached upo

Opportunity for reform is at hand in the ne De-rating Bill. The newer generation of practitione should be encouraged to have some specialty. The should be competent physicians, surgeons, obst tricians, &c., amongst them in each district. The should have held appointments at hospitals an

hould be given charge of beds in the infirmaries of he future. They should be paid adequately for his work, and the remuneration should be on a piece-ork basis. It might very well be on a relief-ticket ystem for those sick that are improvident. General ractice could still be conducted on the best lines f the past, but consulting opinion would be within all of every pocket, and the public would be educated nto realising that their family doctor was still the ound man he was, even if he had to call in the ssistance of a colleague in a branch of medicine in hich he was not specialising. This would be the air and honourable treatment for the general prac-itioner. And the patients would stand to benefit. he contact would remain a personal one still, which s undoubtedly all-important for the very best ervice.

But should a public service come, and the exploita-ion of the profession be carried to the uttermost mits to which it is now tending, the recruitment f medicine will be as successful in this country as or some of the Colonial medical services. Succeeding enerations will resist the lure of becoming underpaid xploited clinical machines, even though they might uspect themselves as being a sop in the political ame. I am, Sir, yours faithfully,

London, W., Jan. 12th, 1929. DEEPLY INTERESTED.

Obituary.

THOMAS EDWARD HOLMES, M.D. CAMB., D.P.H.

THE public health service is deprived of a capable and loyal member by the death of Dr. T. E. Holmes at the early age of 53. As medical officer for the county of Nottingham for the past five years he had borne increasing responsibilities under increasing disabilities of health, but continued to discharge his duties until almost the end of his life.

Son of the late Edward Holmes, chief constable of Leicestershire, he started his medical education at Cambridge, where he took a second class in the Natural Sciences Tripos in 1897. Thence he went on to Guy's Hospital and soon made his mark as a student. On graduating in 1900 he held a succession of appointments to the resident staff; they included that of ophthalmic surgeon, and for many years ophthalmology was of special interest to him. From London he went to Bristol, where he became assistant physician and pathologist to the Royal Hospital for Sick Children, and these and other medical experiences gave him an unusually wide basis for the public work that next received his attention. Appointed school medical officer for Nottinghamshire, he had already acted as deputy for the county M.O.H., the late Dr. Henry Handford, when his work was interrupted by the war. Holmes joined the Royal Army Medical Corps with a temporary commission, but on retiring with the rank of major returned to Nottinghamshire to his old work. On Handford's retirement he succeeded him as medical officer, after a trying period during which the county council tried to fill the vacancy by finding a candidate who would accept a salary below the usual scale. The council's attitude cannot have made the tasks of office more congenial, especially to a man of Holmes's retiring and sensitive disposition; but despite such difficulties and, later, the handicap of poor health, he was able to accomplish many of the schemes which he had planned, and his faithful work is bearing fruit in many directions.

Dr. Holmes leaves a widow with one daughter.

SIR DAVID MAURICE SERJEANT, K.B.E., M.D. ST. AND.

Sir David Serjeant, who died last Saturday, was, we believe, the oldest member of the medical profession in this country, being within a few days of his ninety-ninth birthday. The career thus closed was one of exceptional variety and interest. Born in Huntingdonshire in 1830, the son of a lawyer, Serjeant was early apprenticed to a surgeon in Peterborough, but at the age of 22 left medicine behind for the time being and set out for Australia, where he arrived in time to play in the two first inter-colonial cricket matches. Refusing settled employment, he set out for the goldfields and prospected there for a year or more, but the chances of pioneer life sent him back to Melbourne to turn his hand, after the fashion of the time and country, to all sorts of trades. In 1859 he returned to England and set his mind to medicine at Guy's Hospital, whence he qualified as M.R.C.S. and graduated at the University of St. Andrews in 1862. Joining the P. and O. service he went East again as ship's surgeon and spent many years in this employment before finally returning to England to take up practice in Camberwell. His principal work was found when he was appointed district medical officer and public vaccinator with charge of what is now St. Giles's Hospital. This post he held for a great many years, and he even returned to the practice of medicine during the late war. In 1922 he was created K.B.E.

Sir David Serjeant became medical officer to the Camberwell National Reserve in the early days of his medical practice, and claimed to be the oldest British Volunteer. He married in 1872 Helen, daughter of the Rev. Robert Dear, and had a son and three daughters, one of whom is a member of the medical profession.

WILLIAM LATIMER STOREY, M.D. R.U.I.

THE medical profession in Belfast sustains a sad loss by the death on Jan. 5th of Dr. W. L. Storey. A son of the late John Storey, J.P., of Ballmamore, County Leitrim, he was born in Quebec in 1861, and was educated at Queen's College, Belfast, graduating as M.D. in the Royal University of Ireland in 1889. His life was spent in general practice in Belfast, where he took a lifelong interest in medical societies and was for many years the energetic hon. secretary of the local division of the British Medical Association and hon. librarian of the Ulster Medical Society. To both of these he contributed various papers, some scientific, others in lighter mood, but all of them remarkable for literary style, evidence of wide culture, and a rich gift of kindly humour. Of a somewhat shy and retiring disposition he was deservedly popular with his medical colleagues, who appreciated his sound judgment, his loyal friendship, and his quick wit. He married, in 1890, Elizabeth, daughter of William Betty, of Cappy House, County Fermanagh, and she survives him with a son and a daughter.

WE regret to record the death of two brothers, ARTHUR BROWN SMITH and SYDNEY MCKENDRICK SMITH, whose work seemed to be of much promise and whose contributions to the literature of radium therapy had already begun to attract attention. Of twin birth and about 30 years of age, their careers were closely bound together. Thus, after graduating in medicine at Edinburgh in 1923, they both secured resident appointments at Addenbrooke's Hospital, Cambridge, and both studied the technique of radium treatment at Paris and Brussels and later in Sweden. In 1926 Dr. A. B. Smith took the diploma of F.R.C.S. Edin. and soon afterwards the brothers settled down in a joint practice in Harley-street, also seeing patients by arrangement in Edinburgh. A short book which they published in 1927 on "Radium in Cancer and the Surgery of Access" was useful especially because it showed the necessity for collaboration between surgeon and radiologist. Although their knowledge at this stage was necessarily derived largely from Continental authorities, there was reason to hope that increasing experience of radium would enable them to produce valuable original work. They had been for some time associated with the joint radium committee of hospitals connected with the University of Sheffield, in the capacity of honorary advisers.

Medical News.

UNIVERSITY OF CAMBRIDGE: *Pinsent-Darwin Studentship.*—Dr. R. A. McCance, of the pathological department of King's College Hospital, has been appointed to this studentship for a period of three years from Feb. 1st, 1929. His predecessor, the first holder of the studentship, was Dr. R. D. Gillespie, who has been investigating the relationships of traits of personality to psychoneuroses and the criteria for the differentiation of types of depression.

UNIVERSITY OF LIVERPOOL.—At a recent examination the following candidates were successful:—

DIPLOMA IN PUBLIC HEALTH.

R. M. Jones, J. Litt, F. R. O'Sheil, and J. T. C. Roberts.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a quarterly meeting of the Council on Jan. 10th, Sir Berkeley Moynihan, the president, in the chair, the first award of the Hallett Prize was made. In pursuance of a report from the Board of Examiners in Anatomy and Physiology for the Fellowship, regarding the result of the Primary Examination for the Fellowship concluded on Dec. 14th, this prize was awarded to Shantilal Jamnadas Mehta, M.B., of Bombay University and Middlesex Hospital. The Hallett Prize was instituted as a tribute to the services of Sir Frederic Hallett, late secretary of the Examining Board in England, during his 50 years' service with the College.

The diploma of Fellow was conferred upon James Eastwood Sykes, M.B. Liverp., Liverpool and St. Bart.'s, who has passed the requisite examinations and has complied with the by-laws.

The diploma of Member was conferred upon the following who have passed the necessary examinations: M. K. Gyi, Guy's; J. F. V. Lart, Camb. and St. Thomas's; B. W. Rycroft, St. Andrews Univ.

The undermentioned diplomas were conferred (jointly with the College of Physicians) upon the following candidates:—

Diploma in Laryngology and Otology.—M. I. Ashmawi, A. Blagoff, N. M. Eadie, M. Husnain, N. H. Meacle, H. V. O'Shea, H. M. Petty, S. Roy, E. C. Tamplin, and W. L. Thomas.

Diploma in Psychological Medicine.—R. W. Armstrong, Eileen A. Chennell, A. Craig, H. Hinchco, Phyllis M. Horton, D. L. McCullough, D. Menzies, J. E. Nicole, Muriel L. M. Northcote, Eveleen J. O'Brien, J. C. Ramsay, and C. E. Roachsmith.

POST-GRADUATE COURSE ON NERVOUS DISEASES.—A course on Diseases of the Nervous System will be held at the National Hospital, Queen-square, London, W.C., from Jan. 28th to March 22nd, consisting of 32 clinical lectures and demonstrations at 3.30 P.M. on each week-day except Wednesday and Saturday, together with teaching in the out-patient department at 2 P.M. daily (except Saturdays), and pathological lectures and demonstrations at noon on Mondays. Eight lectures on the Anatomy and Physiology of the Nervous System will be given at noon on Fridays if there are enough applicants, and 12 clinical demonstrations, chiefly on methods of examination of the nervous system, have been arranged to take place at noon on Tuesdays and Thursdays. Further information may be had from the Secretary of the Medical School at the Hospital.

BRITISH EMPIRE CANCER CAMPAIGN.—At a meeting of the Council on Jan. 14th, with the Marquis of Reading in the chair, the following were invited to become Members of the Grand Council: Mr. Malcolm Donaldson (St. Bartholomew's Hospital), Mr. R. G. Hogarth (Nottingham), Sir Ernest Swinton (Professor of Military History at Oxford), and Mr. Cecil Rowntree (Cancer Hospital).—Grants made included a sum not exceeding £2500 for cancer research at St. Bartholomew's Hospital, £150 to Prof. A. J. Clark for radiological research at Edinburgh, and a contribution of £100 towards statistical investigations by the Yorkshire Council of the Campaign.—The Grand Council confirmed the recommendation that two prizes of £500 each, with an appropriate medal, should be offered in the years 1931 and 1933 respectively for the best original piece of work carried out in the British Empire on the investigation of cancer. The prizes will be known as the Garton Prizes and Medals and the actual subjects will be chosen by the Investigation Committee of the Campaign. The competitors may be either single research workers or a team of scientists working together.—Vacancies on the Scientific Advisory Committee were filled by nominations through the Royal Society—namely, Dr. Mervyn Gordon, F.R.S., Mr. J. C. Drummond, D.Sc., and Prof. Sidney Russ, D.Sc.

HUNTERIAN SOCIETY. — The banquet to commemorate the 201st anniversary of the birth of John Hunter will be held at the May Fair Hotel, Berkeley-street, London, W., on Thursday, Feb. 14th, at 7.15 for 7.30 P.M.

THE death is announced of Dr. Henry Selfe Bennett, the last surviving son of Sir Risdon Bennett, at his residence in Upper Berkeley-street on Jan. 13th, aged 81.

ELIZABETH GARRETT ANDERSON HOSPITAL.—The Downs School, Seaford, have promised to endow a bed at the Elizabeth Garrett Anderson Hospital. The Queen will visit the hospital in the spring to open new extensions.

ANCOATS HOSPITAL.—Last year Ancoats Hospital, Manchester, treated 21,228 accident and emergency cases. With only 114 available beds 2589 in-patients were treated and to meet the demands upon the hospital at least a further 100 beds are needed.

PAY BEDS AT WESTMINSTER OPHTHALMIC HOSPITAL.—Fourteen rooms for paying patients, together with a patients' sitting-room, have been opened at this hospital. A children's department is now being prepared, the walls covered with tiles illustrating nursery rhymes.

BIRMINGHAM GENERAL HOSPITAL.—Pending the erection of a new hospital adjoining the University at Edgbaston, the governors have decided to meet the prevailing congestion by providing temporary buildings with at least 40 beds and a new casualty department on the site of St. Mary's Churchyard. A maximum of 30 beds are to be set aside for patients already admitted owing to accidents or emergencies or because the treatment they require can be given only at a general hospital and are in a position to pay for the entire cost of their treatment. A periodical census has shown that there are usually 30 such patients in the hospital, and they will now be asked to pay for their treatment and a limited fee to the member of the medical staff in charge of them.

ROYAL SALOP INFIRMARY.—In accordance with a custom dating back 182 years the annual Royal Salop Infirmary service was held in St. Chad's Church, Shrewsbury, on Sunday week. The service is held in the same week as the annual ball of the Shrewsbury Hunt Club, and it is the rule that the plates for the collection should be held by a recent Shropshire bride and a débutante at the hunt ball. This year the bride was Lady Stanier, the wife of Sir Alexander Stanier, and the débutante Miss Agnes Colville of Coton Hall, Bridgwater. Custom requires that they shall be attended by "two gentlemen of distinguished rank and fortune" in the county. This year these gentlemen were Mr. John Donaldson-Hudson, son of Lieut.-Colonel R. C. Donaldson-Hudson, chairman of the infirmary board, and Mr. Rex Holcroft, of Eaton Mascott Hall, and the collection amounted to £407. The infirmary has ended its year with a deficiency of £1200 on an expenditure of £18,800.

NATIONAL COUNCIL FOR MENTAL HYGIENE.—A series of eight lectures will be delivered in the Lecture Room of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on Wednesdays at 5 P.M. The first three lectures on Jan. 23rd, 30th, and Feb. 13th have as group title Dangerous Ages, and are to be delivered respectively by Dr. J. A. Hadfield (Childhood), Dr. H. Crichton-Miller (Youth), and Dr. Helen Boyle (Middle Age). On Feb. 20th Dr. Letitia Fairfield will lecture on Efficiency and Deficiency, and on the 27th Dr. W. A. Potts on the Irresistible Impulse. The three concluding lectures on March 6th, 13th, and 20th will be given by Dr. Bernard Hart, Sir Maurice Craig, and Dr. C. H. Bond, the subjects being the Minor Mental Disorders of Every-day Life, the Problem of Nervous Breakdown, and the Mental Hospital of To-day. Tickets may be obtained from the secretary of the Council at 78, Chandos House, Palmer-street, London, S.W. 1.

THE LANCET: SUBSCRIPTION RATES.

INLAND	One Year	£2 2 0
	Six Months	1 1 0
	Three Months	0 10 6
ABROAD	One Year	2 10 0
	Six Months	1 5 0
	Three Months	0 12 6

Subscriptions not paid in advance are charged out at the published price of 1s. per copy, plus postage. Cheques and P.O.'s (crossed "Westminster Bank, Ltd., Covent Garden Branch") should be made payable to THE MANAGER THE LANCET Offices, 423, Strand, London, W.C. 2.

Medical Diary.

Information to be included in this column should reach us proper form on Tuesday, and cannot appear if it reaches later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Burlington House, Piccadilly, W.

THURSDAY, Jan. 24th.—4.30 P.M.—*The following papers will be read:* D. Denny-Brown: On the Nature of Postural Reflexes. D. Denny-Brown: The Histological Features of Striped Muscle in Relation to its Functional Activity. (Both communicated by Sir Charles Sherrington.) W. S. Stiles: The Effect of Glare on the Brightness Difference Threshold. (Communicated by Sir John Parsons.) L. J. Harris: The Combination of Proteins, Amino-acids, &c. with Acids and Alkalis. Part II., Titration Curves of Amino-acids, in presence of Formol. (Communicated by Sir Frederick Hopkins.) *The following papers will be read in title only:* F. W. R. Brambell and G. F. Marrian: Sex-reversal in a Pigeon (Columba livia). J. B. Gatenby and Sylvia Wigoder: The Effect of X Radiation on the Spermatogenesis of the Guinea-pig. (Both communicated by J. P. Hill.) J. B. Gatenby and Sylvia Wigoder: The Post-Nuclear Body in the Spermatogenesis of Cavia corbaya and other Animals. (Communicated by E. S. Goodrich.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

WEDNESDAY, Jan. 23rd.—5 P.M., COMPARATIVE MEDICINE and TROPICAL DISEASES. Special Discussion on Glanders and Kindred Diseases. Speakers: Prof. F. T. G. Hobday, Prof. G. H. Wooldridge, Dr. Minett, Mr. J. W. McIntosh, Mr. E. A. West.

THURSDAY.—8.30 P.M., UROLOGY. Paper: Sir William de Courcy Wheeler: Traumatic Rupture of the Urethra.

FRIDAY.—5 P.M., CHILDREN. (Cases at 4.30 P.M.) Cases will be shown. 8 P.M., EPIDEMIOLOGY. Discussion: Vaccination against Small-pox in the Light of Recent Experience. Openers: Dr. Ledingham and Dr. G. F. Buchan.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, Jan. 25th.—8.30 P.M., Papers will be read by Dr. W. D. Nicol and Dr. G. M. Mackenzie on the Treatment of General Paralysis of the Insane by Pyrotherapy. A discussion will follow.

THE MEDICO-LEGAL SOCIETY.

THURSDAY, Jan. 24th.—8.30 P.M. (at 11, Chandos-street, Cavendish-square, W.) A Joint Debate between the Medico-Legal Society and the Society of Medical Officers of Health (Maternity and Child Welfare Group) on Criminal Abortion, and Measures Necessary to Reduce the Sale of Abortifacient Drugs. The Debate will be opened by Dr. F. J. McCann, who will be followed by Dr. R. A. Lyster, Sir Bernard Spilsbury, Mr. H. Beckwith Whitehouse, and Mr. H. D. Roome.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.

WEDNESDAY, Jan. 23rd.—5 P.M (at St. John's Hospital, 49, Leicester-square). Dr. Goldsmith: The Acnes.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn, W.C.

MONDAY, Jan. 21st.—5 P.M., Sir Arthur Keith: The Anatomy and Evolution of the Human Brain. 4th Hunterian Lecture.

WEDNESDAY.—5 P.M., 5th Hunterian Lecture.

FRIDAY.—5 P.M., 6th Hunterian Lecture.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 21st, to SATURDAY, Jan. 26th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Lecture by Dr. Robert Hutchison: Pitfalls in the Diagnosis of Dyspepsia, on Mon., at 5 P.M.—CHILDREN'S CLINIC, Western General Dispensary, Marylebone-road, N.W. Dr. Bernard Myers: The Nervous Child in our Midst (Cases); assisted by Dr. Mackenzie Wallis. Demonstration: Method of Biochemical Examination of the Blood in Neurotic Children. Mon., at 3 P.M.—ST. MARY'S HOSPITAL, Paddington, W. Mr. Zachary Cope: Demonstration, on Wed., at 2 P.M.—WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Demonstration by Prof. Hugh MacLean on the Medical Treatment of Gastric and Duodenal Ulcer, on Wed., at 4 P.M. The above are free.—QUEEN'S HOSPITAL FOR CHILDREN, Bethnal Green, E. Post-graduate Course in Diseases of Children for two weeks. Further particulars from the Secretary. Telephone: Mayfair 2236.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.

MONDAY, Jan. 21st.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M. Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.

THURSDAY, Jan. 24th.—4 P.M., Mr. Addison: Acute Osteomyelitis.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 22nd.—2.15 P.M., Mr. W. B. Gabriel: Fractures of the Spine with Demonstrations of Old Cases.—3.15 P.M., Dr. C. Gouldesbrough: X Ray Diagnosis of Pulmonary Tuberculosis.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Jan. 25th.—4 P.M., Mr. Andrew Wylie: Tuberculosis of the Larynx.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Jan. 22nd.—5 P.M., Dr. H. G. Adamson: Erythema Multiforme.

THURSDAY.—5 P.M., Dr. J. H. MacLeod: Ringworm Infections.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURE, Manchester.

FRIDAY, Jan. 25th.—4.30 P.M. (at the Whitworth-street West Branch). Dr. Lapage: The Diagnosis and Treatment of Acute Cerebral Conditions in Children.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, Jan. 25th.—3.30 P.M., Mr. Townrow: Clinical Cases.

Appointments.

ROY, DONALD W., M.B., B.Ch. Camb., F.R.C.S. Eng., has been appointed Obstetric Surgeon to St. George's Hospital.

SAINT, J. H., M.D., B.S. Durh., M.R.C.S., Resident Medical Officer to the Freemasons Hospital and Nursing Home.

Vacancies.

For further information refer to the advertisement columns.

Birkenhead General Hospital.—Hon. Physician.

Bradford Royal Infirmary.—Two H.S.'s. Each £150.

Brighton, Royal Sussex County Hospital.—Hon. Medical Clinical Asst. Also H.S. £150.

Cardiff City Mental Hospital, Whitchurch, near Cardiff.—Med. Supt. £1000.

Charing Cross Hospital, W.C.—Asst. Physician.

Chiswick General Hospital, The Mall, Chiswick, W.—Additional Second Hon. Consulting Surgeon.

Coventry and Warwickshire Hospital.—Res. H.S. £125.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. Pathologist M.A.B. Bio-chemist at the Board's Antitoxin Establishment, Sutton, Surrey. £600.

Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.

Great Yarmouth General Hospital.—H.S. £150.

Infants Hospital, Vincent-square, Westminster.—H.P. At rate of £75.

Lancaster, Royal Albert Institution for the Feeble-minded.—Locum Tenens Jun. Asst. M.O. 8 gns. weekly.

Leigh Infirmary, Lancashire.—Res. H.S. At rate of £150.

Liverpool and District Hospital for Diseases of the Heart, 34, Oxford-street.—H.P.

Northampton General Hospital.—Hon. Pathologist.

Nottingham, City Mental Hospital.—Jun. Asst. M.O. £350.

Oxford, Radcliffe Infirmary and County Hospital.—Hon. Surgeon.

Port Said British Hospital.—Res. Asst. M.O. £350.

Portsmouth, Royal Portsmouth Hospital.—Cas. O. At rate of £100.

Princess Louise Kensington Hospital for Children, North Kensington.—Hon. Asst. Surg.

Queen's Hospital for Children, Hackney-road, E.—Asst. Surg.

Rochester, Kent, St. Bartholomew's Hospital.—H.P. At rate of £175.

Royal Army Medical Corps.—Twenty-five Commissions. £500 to £2000.

Royal London Ophthalmic Hospital, City-road, E.C.—Three Out-patient Officers. Each £100.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. Clinical Asst.

Ryde, Royal Isle of Wight County Hospital.—Vacancy on Hon. Medical Staff.

Salisbury, General Infirmary.—Res. M.O. £150.

St. Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

St. Mary's Hospital for Women and Children, Plaistow, E.—Res. and Asst. Res. M.O.'s. At rate of £175 and £120 respectively.

St. Marylebone General Dispensary, 30, Marylebone-lane, W.—Dental Surgeon to L.C.C. School Dental Clinic.

Torquay, Torbay Hospital.—Hon. Obstetric Physician.

West London Hospital, Hammersmith-road, W.—Hon. Obstetric Registrar.

Woolwich and District War Memorial Hospital, Shooters' Hill, S.E.—H.S. At rate of £125.

Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £350.

The Chief Inspector of Factories announce vacancies for Certifying Factory Surgeons at Rugby (Warwickshire), Welwyn (Herts), Holmfirth (Yorks), and at Syston (Leics).

A vacancy is announced for a Medical Referee under the Workmen's Compensation Act for St. Albans, Barnet, Hertford and Watford, Circuits 37 and 38. Applications should reach the Home Office not later than Feb. 2nd.

Births, Marriages, and Deaths.

BIRTHS.

ELKINGTON.—On Jan. 10th, at Stockwell House, Bruton, the wife of Dr. Guy Elkington, of a son.

REID.—On Jan. 10th, 1929, at Burntwood, Lichfield, Staffs, to Dr. and Mrs. William Reid—a daughter.

MARRIAGES.

GOSTWYCK—DAWSON.—On Jan. 9th, 1929, at St. Mark's Church, Connah's Quay, Flint, by Rev. E. J. Davies, Cecil Hubert Gostwyck Gostwyck, M.B., F.R.C.P., D.P.M., Deputy Medical Superintendent, Rampton State Institution, Retford, Notts, son of late Lt.-Col. W. G. Gostwyck, 2nd Batt. Argyll and Sutherland Highlanders, to Brenda, youngest daughter of the late Ralph Mainwaring Dawson, of Fulwood Park, Liverpool, and Mrs. Dawson, Kelsterton Hall, Flint.

DEATHS.

BENNETT.—On Jan. 13th, at Upper Berkeley-street, W., Henry Selfe Bennett, M.B. Camb., aged 81.

BOYD-WALLIS.—On Jan. 7th, at Leas Court-mansions, Folkestone, Albert William Boyd-Wallis, M.R.C.S., L.S.A., in his 90th year.

EVANS.—On Jan. 12th, at his residence, Hampstead House, Seaford, Herbert Norman Evans, M.A., M.B. Oxf., aged 93.

HARTLEY.—On Jan. 1st, Francis William Hartley, M.R.C.S., L.R.C.P., of Heywood, Lancashire, aged 63 years.

SIMPSON.—On Jan. 11th, John Watson Simpson, M.B., Ch.B., D.P.H., of Snitterfield, Stratford-on-Avon.

WATSON.—On Jan. 4th, suddenly, at Strathearn-place, Edinburgh, Major Alexander Oswald Cowan Watson, R.A.M.C. (retired), of Carden-place, Aberdeen.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

INDEX TO "THE LANCET," VOL. II., 1928.

THE Index and Title-page to Vol. II., 1928, which was completed with the issue of Dec. 29th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

Notes, Comments, and Abstracts.

IODINE IN RELATION TO GOITRE.

BY D. W. CARMALT-JONES, M.D. LOND., F.R.C.P. LOND.,

PROFESSOR OF SYSTEMATIC MEDICINE, UNIVERSITY OF OTAGO, NEW ZEALAND; CONSULTING PHYSICIAN, WESTMINSTER HOSPITAL.

PART II.*

Goitre Incidence and Soil Iodine.

If it be true that endemic goitre depends on the poverty of the soil in iodine, then an inverse ratio should exist between the amount of iodine in the soil and the incidence of goitre in any series of districts examined. In such an investigation there are several evident sources of error. It can only be true if iodine deficiency is the only possible cause of goitre, if the iodine available for ingestion is derived exclusively from the local soil, and if perfectly uniform observations are made on all cases examined. These conditions are not realised in practice. Nevertheless, a very searching inquiry has demonstrated a remarkable association between iodine deficiency in the soil and the incidence of goitre in school-children. As stated above, over 90,000 children were examined in 33 districts, from each of which samples of soil were analysed, with about 500 analyses in all. Hercus, Benson, and Carter summarise their results as follows: "The figures for goitre incidence and soil iodine have been plotted as ordinates and abscissæ respectively . . . and a smoothed curve has been drawn through the points obtained. So closely do most of these points lie to the curve that it is apparent that an intimate connexion must exist between the amount of iodine in the soil and the incidence of goitre." A few instances only can be given here. In South Canterbury over 5000 children were examined, 62 per cent. of them had goitre, and the soil contains 4 parts of iodine per 10^7. In Taranaki, again more than 5000 children were examined; Taranaki soil contains 166 parts of iodine per 10^7, and the incidence of goitre was 7 per cent. These are the extreme cases. As an intermediate instance, Wellington soil has 40 parts of iodine per 10^7, and 25 per cent. of goitres were found in more than 2500 children. With rare exceptions, a similar inverse ratio is found throughout the country. The very difficult chemistry in these observations was carried out by Mr. C. L. Carter, M.Sc. The geological problems involved were investigated by Prof. W. N. Benson, and a single instance of the observations made must suffice. Canterbury has a very high goitre incidence; the Canterbury Plains consist very largely of river gravel with very little colloid, and contain nothing to hold soluble salts against leaching. The plains are crossed by many great rivers and the soil is very thoroughly leached; this, no doubt, accounts for the small amount of iodine in it, which is accompanied by a 60 per cent. incidence of goitre in school-children living on the products of the soil.

The establishment of this inverse ratio between goitre incidence and soil iodine is evidently of great importance in the inquiry into the ætiology of endemic goitre. It does not, however, indicate how the iodine is obtained by animals, whether by food or water, and a further research was conducted by Hercus, in association with K. C. Roberts as chemist, into the iodine content of foodstuffs raised on iodine-rich and iodine-poor soils respectively. This established that the essential iodine is normally derived from foods, though a deficiency may on occasion be made good by a water-supply which happens to contain iodine from any source such as iodine-bearing rocks or, as in the case of Lyttelton, from the sea. Such instances are, however, quite exceptional.

	Goitrous district.	Non-goitrous district.
	Iodine per kilo.	
Grass	47γ	64γ
Lettuce ..	12	24
Beef	9·5	16
Eggs	56	137

The research is of the first importance in the rational preventive treatment of endemic goitre, since it lays particular emphasis upon the minute amounts of iodine which

* Part I. appeared last week.

mark the difference between an adequate and an inadequate supply, and it is important that added iodine shall not exceed physiological needs. Specimens of all the common articles of food, obtained from goitrous and non-goitrous districts, have been assayed for iodine, and the iodine content was found to vary sometimes as 2 to 3, sometimes as 1 to 2, and occasionally even more widely. The instances shown in the above table are taken from Hercus and Roberts's paper.

It is thus seen that in ordinary rations the actual weight of iodine ingested in the two districts does not differ very widely, and the actual iodine intake per person per day has been estimated. The iodine content of the entire diet of 40 persons was estimated for a fortnight in Canterbury, a goitrous district, and also in Taranaki, a non-goitrous district. The result was surprising; in Taranaki the mean iodine intake per person per day is 35 γ, in Canterbury it is 20 γ. That is to say, the ingestion of 15 γ iodine daily makes the difference between a goitre incidence in school-children of 7 per cent. in Taranaki and 60 per cent. in Canterbury. The estimated daily requirement of iodine for the proper functioning of the normal thyroid is estimated at 30 γ.

The conclusion of this series of investigations is that endemic goitre in New Zealand is due to deficient iodine in the soil, which is reflected in deficient iodine in the food, a deficiency of such an infinitesimal amount as 15 γ daily being effective.

The Amount of the Prophylactic Dose.

This being so, the obvious prophylactic treatment of the condition is the addition of iodine to the diet, as sodium chloride is universally added. This is, of course, no new thing; what is new is the recognition of the minute amounts of iodine required. Failure to recognise it led to the breakdown of several attempts at prophylaxis in the middle of the nineteenth century. Marine and Lenhart (1917) gave school-girls 4 g. of sodium iodide over a period of ten days in two terms, with good results. Hercus and Baker (1921) gave grs. 40, 60, and 120 per annum according to age, with fair results, and without harm. These doses are immensely in excess of physiological requirements, but it appears that in the young no harm is likely to result; only so much iodine as is needed is taken up and the excess is rapidly excreted in the urine. It is otherwise with established goitres in adults, and it is of great importance that prophylactic iodine should be made universally accessible and that it should not be given in excess of physiological requirements. The obvious method seems to be the addition of iodine in suitable amounts to the common salt which has to be added to diet for very similar reasons. Several brands of "iodised salt" are on the market. That sanctioned by the New Zealand Government contains 4 parts per million of potassium iodide. The normal consumption of salt is stated to be about 6 g. per diem—that is, 6 million γ; using iodised salt this should give a daily consumption of 24 γ of potassium iodide, enough to make up the difference between the iodine intake in Taranaki and Canterbury.

Hercus has carefully investigated this method of prophylaxis for any possible bad results. He gave an enclosed population in an institution a salt containing 8 parts of potassium iodide per million. After 18 months no normal children had become goitrous, nearly 70 per cent. of the existing goitres had decreased in size, and there had been no "toxic" cases. It appears, therefore, that iodised salt, 4 parts per million, is of adequate strength and perfectly safe from any risk, and this method of administration is the nearest approach possible to the ingestion of food of natural adequate iodine content.

The Graver Manifestations of Iodine Deficiency.

Simple goitre is the adaptation of the thyroid gland to a particular environment in which the element iodine is not present in adequate amount. The adaptation made may be sufficient to preserve health and no consequences may ensue except a certain unsightliness, but it is also possible that the increase in size may be so great as to cause pressure on important structures, chiefly the trachea. But when a goitre is present there is always the risk of thyroid function being changed, either to excess or defect, so that both hyperthyroidism or "toxic goitre" and hypothyroidism or "myxœdema" may occur. The sequence of events in these conditions and the associated histological changes in the thyroid have been closely studied by Drennan. A normal thyroid is not a uniform structure; parts of it are "hyperplastic," a state called by some observers "active secretory," and other parts are "colloid," resting or storing. The hyperplastic parts are producing and issuing hormone, while the colloid parts lay up a store containing iodine which acts as a reserve during periods of stress or temporary deprivation of iodine. When iodine is not supplied in sufficient amount the thyroid responds to this stress both by hyperplasia, actively secreting without storage, and by increased colloid, increasing the size and number of its alveoli and filling these with colloid at a low iodine concentration; either condition may preponderate. This is the normal response of the thyroid to deprivation of iodine and may be present histologically without any change visible to the naked eye. It has to be considerably advanced before an actual "goitre," *guttur tumidum*, can be detected. A goitre may be called "hyperplastic" or "colloid," but both conditions are to be found somewhere in the gland. Further, the enlargement is not necessarily uniform; isolated masses of either hyperplastic or colloid tissue may occur and are generally called "adenomata." When these changes have occurred there is great liability to hæmorrhage, cyst formation, fibrosis, or atrophy. Drennan recognises three possible variations when the normal thyroid is deprived of iodine: (1) diffuse colloid enlargement, (2) nodular enlargement, and (3) diffuse hyperplasia.

Probably the goitres found among school-children are chiefly in the stage of diffuse colloid enlargement. Many of these are curable by iodine, and revert fairly rapidly to normal; they take up as much iodine as they require and reject any excess, without showing toxic symptoms. In older persons any excess of iodine in treatment is liable to induce toxic symptoms—tachycardia, sweating, nervousness, and possibly exophthalmos. Toxic symptoms do not always or necessarily occur, but they do sometimes, and there is a risk of them. Many forms of stress make heavy demands on the thyroid; menstruation and pregnancy produce actual enlargements, though not great ones, and probably such strains as those induced by university examinations and the like act similarly in young adults. If any excess of iodine be given to a person whose thyroid is accustomed to function with a small allowance of iodine at a time when a heavy demand is being made upon it, toxic symptoms may be produced, presumably because material is supplied for the production of an excess of thyroxin.

Some thyroids become toxic without any excess of iodine; how that comes about is not clear. Iodine treatment may cure diffuse colloid goitre, but iodine in excess may induce toxic symptoms, and that is why prophylactic iodine in salt must be kept down to the irreducible minimum. Much the same is true of the nodular enlargement; on the whole, nodular enlargements more frequently show toxic symptoms, "toxic adenoma," and often take the more serious form of Graves's disease. The actual amount of thyroid tissue present in any given case is an important factor in the precipitation of toxic symptoms. On the other hand, the adenomata are also liable to atrophy and hypothyroidism, up to complete myxœdema. It is perhaps questionable if the condition of diffuse hyperplasia results from iodine deficiency, but there are cases which support it. These are the cases which have shown no goitre until well into adult life. It is suggested that up to that time they were able successfully to compensate for iodine deficiency without visible enlargement. They suddenly develop goitre, with toxicity and often exophthalmos, and constitute "primary Graves's disease." This is not infrequent at the menopause in women, and it may be that when the demand for thyroid activity is thus stopped the thyroid produces a relative excess of thyroxin which induces the toxic symptoms.

"Toxic goitre" is an exceedingly difficult subject. Every case of goitre submitted to stress does not become toxic, and it is not suggested that its occurrence is wholly to be explained by deprivation or excess of iodine, but there are undoubtedly cases in which toxic symptoms may be induced by iodine, so that the greatest care is necessary in its use. A few instances may be recalled in which the exhibition of iodine was followed by toxic symptoms in cases of goitre.

CASE 1.—A woman medical student, with a simple goitre, when working at high pressure in her fourth year of study, was given potassium iodide, grs. 15, thrice daily for the goitre. Graves's disease, ultimately requiring partial thyroidectomy, rapidly supervened.

CASE 2.—A male medical student, aged 23, with a large soft goitre, took grs. 200 of potassium iodide in nine months, rather less than a grain a day. At the end of this time the goitre had disappeared, but tachycardia, tremors, and exophthalmos were present, which subsided in several months without operation.

CASE 3 (by courtesy of Dr. Frank Fitchett).—The chest of a patient with goitre suffering from pleural effusion was painted by tr. iodi, and toxic symptoms supervened.

CASE 4 (also Dr. Fitchett's).—A patient suffering from obesity, which concealed a goitre, received potassium iodide in the prescriptions, and intense hyperthyroidism was induced.

Dr. Fitchett has also reported three cases of students from a ladies' college who showed signs of hyperthyroidism after the introduction of iodised salt having the strength of 1 part of potassium iodide in 5000 (50 times the strength now authorised by the New Zealand Government).

The iodides are drugs in common use in the treatment of bronchitic and rheumatic conditions; the question arises

how far their prescription may be responsible for the induction of toxic symptoms in cases of goitre.

The ætiology of endemic goitre in New Zealand is believed to be understood, and it is also believed that when the profession and the public fully realise the position it will be prevented. Toxic goitre is a far more difficult matter, and these remarks are only an attempt to apply the knowledge which exists about simple goitre to the toxic problem.

PLASMOCHIN IN MALARIA AND BLACKWATER FEVER.

Dr. Drenowsky[1] has found plasmochin useful in treating malaria in country practice in Bulgaria; it has not the unpleasant taste of quinine, does not cause ringing in the ears or headache, and though in the treatment of 209 cases it did cause—in adults, and about the fourth or fifth day—diarrhœa five times, blueness of the lips and gums three times, and vomiting once, these unpleasant symptoms passed quickly away when administration of the drug was stopped. It is issued in the country districts in Bulgaria by the "quinine distributors," who are taught to give plasmochin to tertian and quartan cases, but plasmochin compound (plasmochin 0·01 g., with 0·125 g. quinine) to subtertian patients, the dose of plasmochin never to exceed 0·01 per kg. of body-weight. This works out at about grs. 10 for a man of 10 st. They must also themselves put the dose into the mouths of the patients, and watch for and report any unpleasant sequels. Good results are claimed. Treatment is given for six days after which the blood is again examined. Should the cure be incomplete, treatment is repeated for six to eight days, and after a five-day pause another course may be given if required. The swelling of the spleen quickly diminishes. Of the 209 cases above-mentioned, three-quarters were said to be cured (of tertian 81, of quartan 61, of subtertian 50 per cent.). Chronic carriers can most hopefully be tackled in winter, when 80 to 90 per cent. of successes are claimed. Four cases of blackwater fever all recovered, pyrexia being lost in three days, hæmaturia in five. Gravid women, Dr. Drenowsky says, take plasmochin without harm, a very important matter, and the drug is useful in the malarial diarrhœa of children. As there are quinine-resisting parasites, so some resist plasmochin. Dr. P. Talianidis reports[2] on the 80 cases of blackwater fever he has treated at Salonica among the refugees during four years ending in December, 1927. Cases appeared mostly in autumn and January—i.e., in the subtertian season. The disease was most often seen in hard-working, poorly fed men, particularly those who took quinine irregularly. He has most confidence in plasmochin in treatment. Of 14 patients treated with this drug, only two died, whereas 21 died in a series of 30 who were given quinine.

CHOCOLATE AND COCOA.

Messrs. Cadbury Bros., Ltd., have this year produced chocolates in several new assortments additional to their well-known brands. From the novelties the firm, it appears, caters for those who like hard centres by an assortment under that name, while for those who prefer soft centres there are other kinds. The samples sent to this office include also specimens of the new chocolate sandwiches in convenient packages, and of Bournville Cocoa. All these delicacies are produced under hygienic conditions, and are known to our readers to be of high quality, while nutritional value has been always under consideration.

LANE'S SCHOOL OF ANATOMY.[3]

ALL familiar with the story of medical education, as the early attempts towards standardisation became effective at the end of the eighteenth century, know the prominent part that was played, especially in London, by the private

(*Continued at foot of next column.*)

THE KING'S ILLNESS.

OFFICIAL BULLETINS.

(*Continued from p. 112.*)

THE following is the text of the official bulletins which have been issued during the past week and signed by Sir Stanley Hewett and Lord Dawson of Penn:—

WEDNESDAY, JAN. 9TH. 8.15 P.M.

The King has had a quiet day. The local conditions make steady progress and there is a slight increase of strength. No further bulletin will be issued till to-morrow evening. (Signed also by Sir Hugh Rigby.)

THURSDAY, JAN. 10TH. 8.15 P.M.

The King has passed a quiet day and there is no change to report in His Majesty's condition. The next bulletin will be issued to-morrow evening.

FRIDAY, JAN. 11TH. 8.15 P.M.

The King has had a restful day. There is no change to report in His Majesty's condition. The next bulletin will be issued to-morrow evening.

SATURDAY, JAN. 12TH. 8.20 P.M.

The King has had another restful day and otherwise the condition of His Majesty remains unchanged. The next bulletin will be issued on Monday morning next.

MONDAY, JAN. 14TH. 11.30 A.M.

His Majesty is making slow progress. The next bulletin will be issued to-morrow evening. (Signed also by Sir Hugh Rigby.)

TUESDAY, JAN. 15TH. 8 P.M.

The King has had a quiet day. The progress previously noted, though slow, continues. The next bulletin will be issued on Thursday morning.

(*Continued from previous column.*)

schools of anatomy. The last of these institutions, popularly known a hundred years ago as "Lane's School," has been now made the subject of an interesting note by Mr. R. R. James, ophthalmic surgeon to St. George's Hospital, the institution with which the school was specially connected. The school was founded by Mr. Samuel Armstrong Lane, a pupil at St. George's Hospital, of Sir Everard Home in 1830, and it continued to exist in a fairly flourishing condition until 1854. It was in some respects the lineal descendent of the school in Great Windmill-street, honourably associated with the names of the two Hunters, Matthew Baillie, James Wilson, Benjamin Brodie, and Cæsar Hawkins, among others. This institution came in some way under the management of Lane, when it was transferred to Grosvenor-place to meet the needs of the students of St. George's Hospital, but almost contemporaneously an anatomical school was started within the hospital, so that there were, for a period, two schools existing within a few yards of each other. Mr. James's pamphlet, several chapters of which have appeared at times in the *St. George's Hospital Gazette*, is especially interesting in the light that it throws on the violent bickering that was quite usual among hospital staffs in those days. It would seem, from Timothy Holmes's "Life of Sir Benjamin Brodie," that at the Great Windmill Street School Brodie had been the pupil of James Wilson, while the son of James Wilson became associated with Lane in starting the anatomical school in Grosvenor-place. This was unfortunate for Lane, as inimical relations existed between Brodie and the son of his former master, and a bad understanding with the all-important Brodie affected Lane's chances of being elected upon the staff of St. George's Hospital. How this resulted in the transference of Lane's school to the new St. Mary's Hospital is explained in Mr. James's interesting chapter on medical history. He gives us a picture of hospital life and medical training as they existed up to the middle of the nineteenth century which bears no resemblance to anything any living practitioner can remember, and once again demonstrates how closely associated the medicine at the beginning of the nineteenth century was with that of the eighteenth century, and how complete the transformation in views and practice was which followed rapidly upon the vast medical progress dating from 1850.

An Address

ENTITLED

SORE FINGERS AND SUCH TRIVIALITIES.

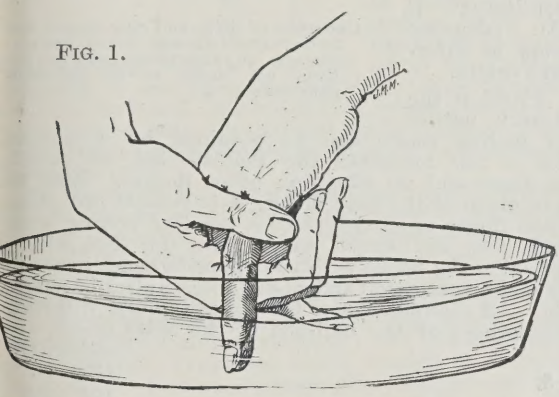
Delivered before the Liverpool Medical Institution

BY R. KENNON, M.D. LIVERP., F.R.C.S. ENG.,

LECTURER IN PRACTICAL SURGERY, UNIVERSITY OF LIVERPOOL; HON. ASSISTANT SURGEON, LIVERPOOL ROYAL INFIRMARY.

The hangnail, the thorn-pricked hand of the gardener, the needle-prick of the seamstress or surgeon, and the bites of the gnat, lesions too trivial to figure in examination papers, are too often a nightmare in our practices. It is no exaggeration to say that in any large city many valuable fingers are amputated for gangrene which have never been infected. These and others permanently crippled

FIG. 1.



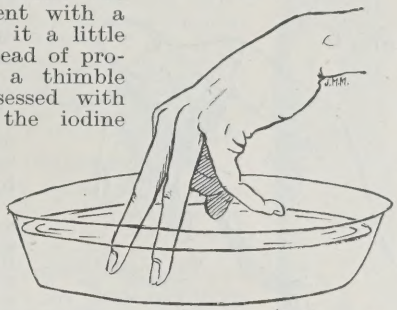
The usual method of soaking a finger, the nail-bed tenderness of the opposite little finger is diagnostic.

might have been saved by a better appreciation of the usual reaction to injury and a knowledge of the destructive action of antiseptics, hot fomentations, and squeezing in search of non-existent pus.

I am not concerned with the infected finger but with its antecedents—the reaction to injury. It is rare for a serious infection to supervene upon the pricked finger of the gardener or in the poor child with a hospital dressing trailing in the mud as he hobbles home with a cut foot. In conformity with modern first-aid knowledge both will have had the wound washed. Experience will show that wounds kept dry suppurate less frequently than those kept moist, so a liberal application of any mild spirit preparation, such as tincture of iodine, may complete the treatment. Some quickly forget their injuries, but doctors, nurses, and the more educated lay people are all too ready to imagine that the thorn or needle has carried germs into the depths, so a vigorous squeeze initiates treatment, to make the part bleed and wash back the organisms. A moment's thought would show that it would be just as sensible to try to squeeze water out of wet socks without first removing the boots. This treatment can only disseminate the organisms beneath the skin, and, by further injuring the tissues, provide a nidus of extravasated blood wherein bacteria may multiply in security from the surrounding lymph and its protective qualities. *Squeezing for pus*, once started, becomes a hobby of patient and practitioner whenever they look at the finger. It is quite easy to recognise such maltreatment in a progressively tender finger: (1) by the circular line of demarcation between the healthy and the congested area; and (2) by the almond-shaped patch of congestion where pinching has been the continuing trauma. I have seen boils on the more accessible parts of the body so strenuously pinched that a black patch of gangrene the size of a sixpence had appeared; if to this a really hot fomentation is added a crop of vesicles will form and so simulate anthrax as closely as vaccinia. In a museum of public health a few years ago there figured a coloured illustration labelled "Anthrax, organisms not found." I wonder how many boils are so treated.

Twelve hours after the injury the patient with a sore finger finds it a little tender, and instead of protecting it with a thimble he becomes obsessed with the idea that the iodine was not strong enough, so into carbolic, lysol, or whatever antiseptic is being boomed by the chemist or the press that unfortunate finger is plunged, all oblivious of the truth that organisms cannot be killed on the body without necrosis of the underlying soft tissues. The analgesic action of the carbolic compounds on the fingers gives a false sense of security to the patient and an anxious time to the doctor, whose danger-sign of throbbing pain is masked. If all goes well the patient will escape with prolongation of finger-tenderness for three weeks or more beyond the normal healing-time. Unfortunately, about the third day the analgesic effect lifts slightly, so more lysol or a hot fomentation is applied, with gangrene as an end-result.

FIG. 2.

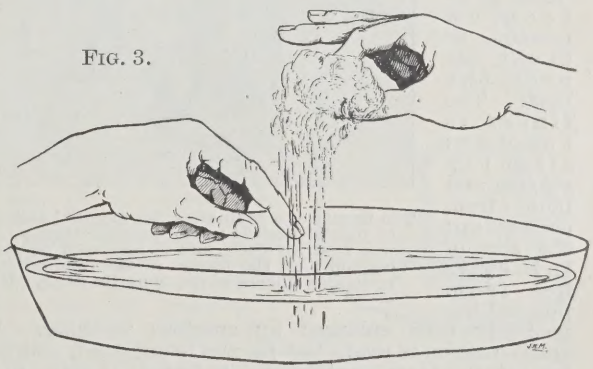


Simultaneous soaking of middle and ring fingers in an injury to either.

Thinking that unless an antiseptic stung on application it could do no good, an ex-officer managed to convert the punctate sting of a gnat into an ulcer three inches long and half an inch wide. I trust the consultation restored his faith in the profession and also that another time one of my colleagues will think of lysol before diagnosing gumma.

It is astonishing how experience differs. Some have never seen any harm done by the carbolic series, whereas I have seen three fingers and an arm amputated for it. Naturally, therefore, I suspect it in all indolent

FIG. 3.



Tenderness of thumb and index-fingers of opposite hand in cases where cleansing in hot lotion has been prescribed.

wounds where necrosis and not pus-formation is the outstanding feature. The atrophic taper finger of the less severe case, once seen, is not likely to be forgotten.

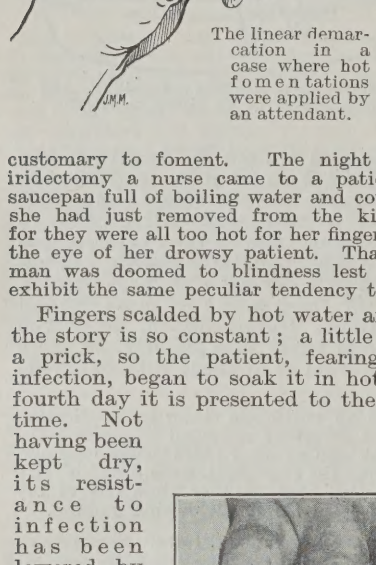
FOMENTATIONS.

It is not, however, to the mechanical irritation of pinch, squeeze, or grip, nor to the chemical irritation of lysol that the prize must be given for the production of the greatest physical pain and misery, but to the *hot fomentation*. The advice to go home and soak a

finger in hot water is criminal. The public interpret this into "the hotter the better," and literally scald their fingers to death. Nor do the shrieks from a casualty department at re-dressing time reveal any advance in the battle against pain.

When lecturing on practical surgery Prof. R. E. Kelly used to point out that a hot fomentation or a cold compress would keep its initial temperature for only two or three minutes after its application and then become, for the remaining two or four hours, a moist dressing at body temperature. What value can two or three minutes' intense heat or cold be to any wound?

FIG. 4.

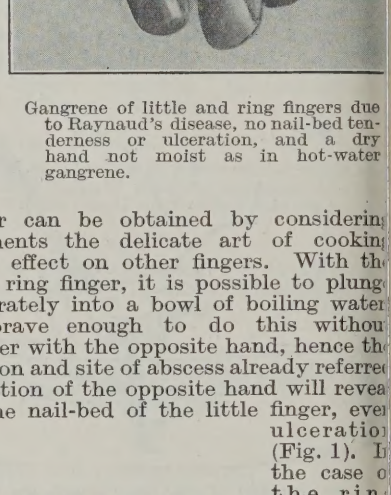


The linear demarcation in a case where hot fomentations were applied by an attendant.

As a student I could not understand why Mr. T. H. Bickerton used ice-water compresses in eye cases. His wisdom may be contrasted with events in another city, where it is customary to foment. The night after a preliminary iridectomy a nurse came to a patient's bedside with a saucepan full of boiling water and cotton-wool dabs which she had just removed from the kitchen fire. Quickly, for they were all too hot for her fingers, she dropped one on the eye of her drowsy patient. That eye was lost and a man was doomed to blindness lest the other eye should exhibit the same peculiar tendency to inflammation.

Fingers scalded by hot water are easily recognised, the story is so constant; a little tenderness followed a prick, so the patient, fearing the possibility of infection, began to soak it in hot water. About the fourth day it is presented to the doctor for the first time. Not having been kept dry, its resistance to infection has been lowered by waterlogging, but rarely is infection present, so great has been the heat. The finger is tender; slightly swollen, and blue from congestion; the site of injury is free from pus and has probably been enlarged by amateur needling. A small incision is made but no pus is obtained, and so fomentations are continued. A few days later the finger is causing anxiety and is the subject of a consultation. At the site of injury a small slough has formed and a little serum is being discharged. The bluish discoloration ends abruptly half way along the proximal phalanx—the line of grip. Into this congested area the medical attendant feels too often convinced that either he or his surgical friend should make a further incision and discover the missing pus. The incision will reveal a deep fascia tinged a beautiful light green from the extravasation of blood pigment, comparable to the discoloration seen on the back of the uterus in pelvic hæmatocele. So long as the tissues are glistening this fascia will recover, often without slough formation. The incision has been a useless one and heals by first intention. If the fascia has lost its glistening appearance the incision will be a useful exit for sloughs. Occasionally the incision will evacuate a few drops of material resembling the "anchovy sauce" of liver abscess. The site at which this pus occurs is usually the line of demarcation, several inches away from the original prick, and not in the centre of the diseased area. The final picture is one of aseptic or dry gangrene due to moist heat; an amputation follows and healing by first intention is the rule—an impossibility if the gangrene were of infective origin.

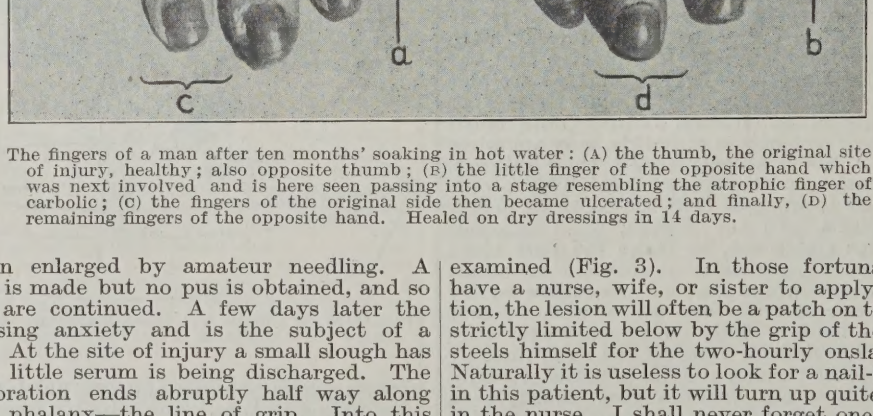
FIG. 6.



Gangrene of little and ring fingers due to Raynaud's disease, no nail-bed tenderness or ulceration, and a dry hand not moist as in hot-water gangrene.

Proof of the deadly nature of boiling water can be obtained by considering for a few moments the delicate art of cooking a finger and its effect on other fingers. With the exception of the ring finger, it is possible to plunge each finger separately into a bowl of boiling water but few are brave enough to do this without gripping the finger with the opposite hand, hence the line of demarcation and site of abscess already referred to. An examination of the opposite hand will reveal tenderness of the nail-bed of the little finger, even ulceration (Fig. 1). In the case of the ring finger it is the middle finger of the same hand that is likely to share the scalding (Fig. 2). If the prescription has been to cleanse the sore with cotton wool whilst soaking then the thumb and index-finger of the opposite hand should be examined (Fig. 3). In those fortunate enough to have a nurse, wife, or sister to apply the fomentation, the lesion will often be a patch on the pricked side strictly limited below by the grip of the patient as he steels himself for the two-hourly onslaught (Fig. 4). Naturally it is useless to look for a nail-bed tenderness in this patient, but it will turn up quite unexpectedly in the nurse. I shall never forget one case in which family relations appeared distinctly strained on my arrival and were made worse by my inquiry as to pain, which the patient forcibly assured me that I should feel if I had a wife and doctor squeezing the sore every few hours looking for pus. Fortunately, an incision appeared necessary, and this, he was assured would obviate the necessity for further squeezing. I felt certain that this finger had also been vigorously

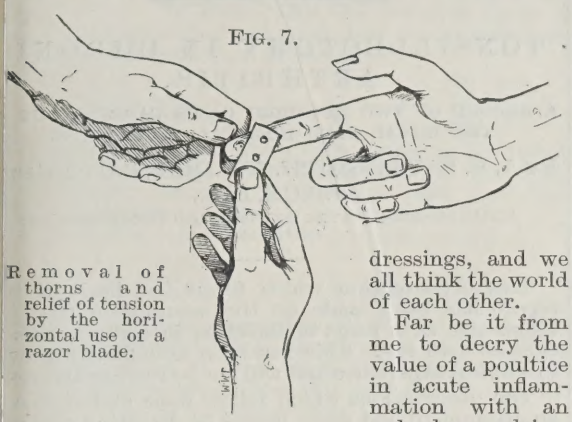
FIG. 5.



The fingers of a man after ten months' soaking in hot water: (A) the thumb, the original site of injury, healthy; also opposite thumb; (B) the little finger of the opposite hand which was next involved and is here seen passing into a stage resembling the atrophic finger of carbolic; (C) the fingers of the original side then became ulcerated; and finally, (D) the remaining fingers of the opposite hand. Healed on dry dressings in 14 days.

calded, but it was too risky to ask. Imagine my joy, s we cleaned the instruments, when the wife apologised or being unable to pick them out of the hot water s her fingers were so tender with applying hot mentations to her husband day and night for the st ten days! The finger healed on cold, moist

FIG. 7.



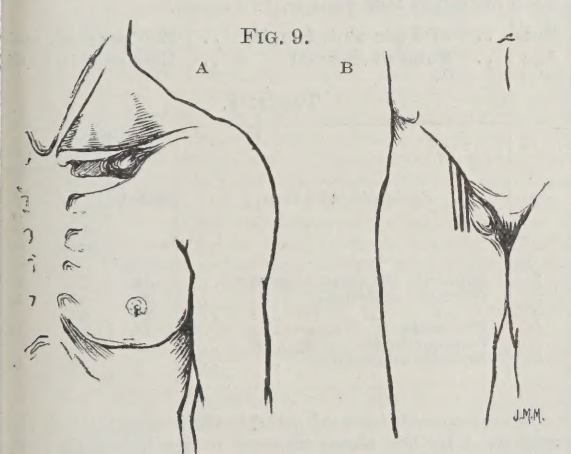
Removal of thorns and relief of tension by the horizontal use of a razor blade.

dressings, and we all think the world of each other.

Far be it from me to decry the value of a poultice in acute inflammation with an unbroken skin. With an open sore it is a very septic application, specially if not renewed each time. Such applications die hard and only recently a friend observed a breast tinged green by natural herbs obtained from the milkman—the cow-dung poultice—for a mammary abscess in 1927.

The last finger I amputated had been poulticed with linseed. Never shall I forget the cloud of steam, as from a Christmas pudding, that greeted me as I exposed the hand, which was swollen enormously from the wrist downwards. Complete loss of the hand appeared imminent—all from a pricked finger that had never suppurated. I waited 24 hours, then amputated the gangrenous finger; the handle-of-the-acquet incision evacuated half a drachm of necrotic pus from the dorsum—a finger-grip abscess—and the

FIG. 9.



(A) The apical gland of the axilla; this site should always be examined, because it is this gland which most frequently suppurates and produces axillary cellulitis. (B) Cloquet's gland, of similar importance to the apical gland of the axilla.

deep fascia was light green in colour. Could the hand be saved? In spite of the so-called pus, that stump healed by first intention; the green dorsal fascia did not slough except just below the styloid process of the ulna, the point of maximum pressure when the finger-grip was changed to a wrist-grip as the size of the poultice was increased. It healed quickly on incision.

Ten months ago a stone-mason developed an abrasion of the pulp of the left thumb, since when nearly every nail has been involved and Raynaud's disease suspected. The moisture of the hand first attracted our attention, for surely a Raynaud's hand would be dry. Then we examined the thumb; it had healed without loss of tissue—also rare in Raynaud. Then came the following story to delight the heart of Sherlock Holmes. For months he had been soaking his fingers in hot water; after the left thumb the little finger of the opposite hand became "septic," then all the finger-nails of the original hand, finally those of the opposite hand; meanwhile the thumb had healed, and with its fellow of the opposite side it remained healthy, being well out of the way of subsequent scaldings. Four days on dry dressings removed all pain. He left hospital in ten days, healed. Note how clearly the little finger of his left hand resembles the atrophic taper-finger of the carbolic days (Fig. 5). Contrast Fig. 6, gangrene due to Raynaud's disease, in hospital at same time.

FIG. 8.

Illustrates the ease with which a small septic focus may be incised after removing the superficial epithelium.

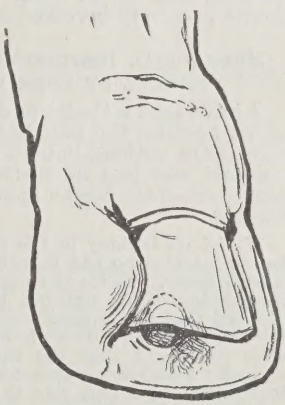
ETHYL CHLORIDE.

A story against myself will suffice. The patient was a doctor; a boil on the back of his finger had commenced to throb, and the hour was late, so we dispensed with an anæsthetist and used ethyl chloride as a local freezing mixture. I opened an infected follicle 5 mm. in diameter, expecting it to separate in three days and heal in a week. It did not heal until a slough three-quarters of an inch long had been extracted by the doctor three weeks later. A slough so big was surely due to the action of ethyl chloride on congested tissue.

THE TREATMENT OF A SORE FINGER.

Keep it dry. Protect it from squeezing by a thimble or celluloidguard. If a thorn is still in do not squeeze. Take a safety razor blade and slice off the over-lying epithelium; this will drag the thorn out and, should the spot suppurate, the denuded area will provide an easy exit for pus and so limit inward spread (Fig. 7). If the finger is throbbing relieve the tension by an incision and then apply moist dressings at body temperature. It is not easy to place these small incisions with accuracy and to avoid the annoyance of seeing the abscess burst two or three days later 1 mm. from the line of incision. Use of the razor blade in a horizontal direction will show up the site of puncture and greatly assist in correctly placing the incision (Fig. 8).

FIG. 10.



The cotton-wool pack beneath the centre of the nail and not its narrow edge, of value in cases of ingrowing toe-nail.

For accurate localisation of an abscess the method adopted by Mr. Frank Jeans is well worth remembering. In kindly thought for his patient he does not brandish a probe, but takes the more homely match. If the centre of the brawny swelling shows a maximal point of tenderness a small collection of pus may be expected; if two maxima are encountered then a larger collection may be expected and the incision must be made between these points. For lines of incision that masterpiece by Kanavel on "Infections of the Hand" should be followed. I owe an early introduction to this book to the late Prof. Thelwall Thomas, whose masterly mind was quick to realise the importance of the work and to distribute it amongst his residents and dressers long before it appeared in the articles and text-books of this country.

Avoid dipping with a pointed knife; the so-called "breast knife" is a safer instrument. Amongst injuries inadvertently produced I recollect a stiff metacarpo-phalangeal joint damaged by an incision in a fruitless search for pus after a stork-bite an inch away. For infected fingers use a general anæsthetic and a tourniquet. Watch lymphangitis; it often subsides without suppuration, and if the lines are broken between the site of injury and the gland, let well alone. Further exploration of the wound, unless there is definite evidence of pus under tension, may turn the scale against the patient. The danger zone is now in the glands.

The epicondylar gland drains the lymph from the little finger and half the ring finger, passing it on with that from the rest of the hand to the axilla. All the axillary glands may be enlarged, but the one most liable to suppurate is the apical gland, because it is liable to be nipped between the clavicle and the first rib (Fig. 9 (A)). A sling should therefore be worn in all cases, and the clinical examination for glands should be completed by gently pressing beneath the middle of the clavicle. In the lower extremity the long axis of the inguinal glands points to the perineum; an unsuspected carcinoma of the rectum may be revealed by this. The femoral glands are much lower in the limb and their long axis points to the toes, but they all enter the iliac glands through the crural canal, and therefore the gland of Cloquet assumes the same importance in infections as the apical gland of the axilla (Fig. 9 (B)). If the glands are enlarged the patient often experiences on the third or fourth day a rigor, rise of temperature, and profuse sweating, as the toxins or organisms previously held up in the gland are poured into the blood stream. This may herald a fatal septicæmia, but fortunately nothing more than a mild rheumatism usually follows. In boils it is often called influenza and figures frequently, together with so-called pleurisy, in the history of perirenal abscess. Do not discard the sling or permit walking until all gland tenderness has disappeared for at least four days, and it is well to remember that the wound is often healed before the glands give trouble, especially in staphylococcal infections.

Greater use should be made of metal cock-up finger splints, discarding these the moment it is realised that the infection is subsiding and that it is wise slightly to prolong healing in order to avoid the stiffening of joints passively involved in inflammatory reaction.

Mechanical Irritation of Nail Growth as a Sequel of Sore Fingers and Toes.

I have seen a typist in danger of losing her employment because the nail had been allowed to grow too soon. On cutting it back she was able to work with comfort and had no further pain because, when the nail reached the tender spot again, good scar tissue had formed.

Whilst on holiday in the South of England I was asked to see a cook who had been tormented for over a year with a sore finger. Twice the nail had been removed and total destruction of the nail-bed had even been proposed. She did not like this suggestion, and, tired of the profession, she kept at home, dutifully cleansing the sore in hot water, with the result that the thumb and index finger of the opposite hand had begun to crack. I recognised that an ingrowing finger-nail was the painful factor, and advised pushing a piece of cotton-wool under the body of the nail in order to lift the pressure off the tender spot. She was cured in three weeks.

For ingrowing toe-nail this cotton-wool pack under the centre of the nail and not under its narrow edge will quickly bring relief, and subsequent square trimming of the nail will prevent recurrence (Fig. 10).

In conclusion, I cannot resist emphasising the damage that is being done by boiling water. Recently I saw a woman with a sloughing carcinoma mammæ, mistaken by her for an abscess. As it was in an awkward situation to foment or soak she had filled the modern wide-necked milk bottle with boiling water and inverted this on her nipple. I have also seen a man with a flexion deformity of the middle finger, the end-result of a knife-cut 20 years ago which took four months to heal and, as he announced with pride, two men to hold it in the boiling water. Abolish boiling water and with it phlegmon.

TONSILLECTOMY IN CHRONIC ARTHRITIS.

A REPORT OF TWO HUNDRED CASES CARRIED OUT AT THE ROYAL BATH HOSPITAL, HARROGATE.

By A. B. PAVEY-SMITH, *M.C.*, M.B., B.Chir. Camb., F.R.C.S. Eng.,
AURAL SURGEON TO THE HOSPITAL AND THE HARROGATE INFIRMARY.

The investigation which forms the basis of this report has been made on the assumption that the tonsil acts as a focus of infection in certain cases of chronic arthritis. This has been abundantly proved by clinical experience and will not be further discussed.

The observations which follow were undertaken as an attempt to find some means of detecting clinically the focally active tonsil, and to discover the type of case most likely to be benefited by its removal. Until these two factors can be fairly accurately determined tonsillectomy for systemic disease must border on the empirical, will be adopted in unsuitable cases, and will prove a source of disappointment.

The 200 cases of tonsillectomy here reviewed have been taken serially, without selection, over a period of six years. I have purposely not included cases done elsewhere, in order to obtain the greatest uniformity in points of diet, technique, and after-treatment. In each of these 200 cases a record was kept of the name, age, sex, systemic condition and its duration, throat history, size and colour of tonsils, crypt contents, condition of the cervical glands, and bacteriological findings. In addition results have been obtained this year in 172 cases.

Sex .. 67·5 per cent. females .. 32·5 per cent. males
Age .. Total average 30 .. Extremes 10 to 64.

Table I.

—	Systemic condition.	Total.	Percentage of occurrence.	
			In whole series.	In males.
1	Subacute rheumatism group ..	54	27	33
2	Infective arthritis C	90	45	43
3	" " D	28	14	5
4	Fibrositis	19	9·5	8
5	Osteo-arthritis	1	0·5	0
6	Neuritis and sciatica	8	4	11

The nomenclature adopted is that originally devised and used by the three mineral water hospitals (Bath, Buxton, and Harrogate).

Group 1 includes subacute cases of, recurrences of, and convalescents from rheumatic fever or "acute rheumatism."

Groups 2 and 3.—"Focal infective arthritis": C indicates that the focus has been located; D that its situation is unknown.

Clinically these cases are of the following type: Onset, at the age of 25 to 40, sometimes acute, often febrile; usually bilaterally symmetrical; at first periarticular; early limitation of movement; smaller joints first affected; fusiform swelling of joints. This category therefore includes many cases of "rheumatoid arthritis" and Still's disease.

The figures are based on the final diagnoses made by the physicians on the patients' discharge. The third column of figures is included to show that sex is not an important influence. The preponderance

of females in "infective D" is due to the inclusion of cases of indeterminate chronic arthritis of atrophic type, the classical "rheumatoid arthritis," which is recognised as affecting women particularly.

Duration.—Several of the subacute rheumatism group were recurrences of an original attack many years before. In such cases the duration given is that of the present attack, and does not include long periods of freedom from arthritis.

Under one year	102 cases.
One to five years	55 ,,
Over five years	43 ,,

I hoped that from a large series such as this some definite clinical picture characteristic of the focal tonsil would emerge. I therefore paid particular attention to five points :—

1. Tonsil history—
   + + = "Related."
   + = Positive.
   0 = Negative.
2. Tonsil colour.
3. ,, size.
4. ,, crypts.
5. Cervical glands.

These five points I regard as the five "landmarks" to be kept in mind when assessing the focal activity of a tonsil, and it was these that guided me in selecting for operation these 200 cases out of over 400 referred to me by the physicians.

History.—Three types were noted :—

1. "Related" (+ +): cases in which attacks of tonsillitis bore a definite relation to the onset or exacerbations of the arthritis.
2. Positive (+): i.e., repeated sore-throats, previous attacks of tonsillitis or quinsy, but unrelated to the arthritis.
3. Negative: "Never any trouble with the throat." With allowances for defective memory and the extremely non-committal attitude, these histories are probably fairly reliable.

Colour.—Redness localised to the tonsil is definite evidence of tonsil infection; general redness of the fauces is usually due to dental sepsis, alcohol, or tobacco; but may mask a tonsillitis. Twenty cases in which the colour was normal showed nothing characteristic in their bacteriology.

Size.—This has been agreed by all observers to be no index of infectivity. I have been unable to find any variations other than could be accounted for by the normal physiological shrinkage with age.

In 30 patients tonsil operations had already been done, in most of them many years previously, and fairly large remains—in some cases apparently intact tonsils—were present. I have always regarded such "remains" with suspicion. The scarred surface may be pale, but the crypts are often full of infective material pent up by the cicatrised crypt mouths. I can find no evidence, however, that they are a greater potential focus than intact tonsils. Their infectivity, however, is more latent, and I should be inclined to advise complete removal of such tonsils in a case of infective arthritis, even though every other point were negative—which is rare.

Crypts.—These are revealed by pus or bleeding on pressure on the tonsil.

Glands.—The key-gland of the tonsil is situated just behind and below the angle of the jaw. Enlargement of these glands can be regarded as definite evidence of tonsil infection, present *or past.*

Tenderness.—This is very rarely met with, even in cases of gross chronic infection. Usually it is only found during or just after acute tonsillitis. It was noted in five cases only.

Associated Infection.—Many cases were edentulous. Some had had extensive extractions some time before with partial improvement of the arthritis. I have made it a rule not to touch the tonsils until dental sepsis has been dealt with. The same applies to purulent nasal or sinus infection.

Bacteriology.—In each case the excised tonsils have been scorched to destroy any surface contamination, cut open, and cultures made from the interior.

Results.—A questionaire was sent out to all patients on Jan. 1st, 1928. The patients were asked to state if the arthritis was cured, improved, unchanged, or worse; 172 replies were received, as follows :—

Cured	35	134	78 per cent. good results.
Improved ..	99		
Unchanged ..	21	38	
Worse	17		

The ratio of good results to bad results is thus 134 : 38. This ratio I have expressed, for comparison purposes, and shall refer to, as the "result percentage"—in this case 78 per cent. These results were reported from three months to six years after the operation. Within these limits the cure or improvement is no transitory affair. The results for infective arthritis in the first three years vary by only 5 per cent. from those in the last three years.

Cross-checking the Figures.

In the search for some "formula" for the focal tonsil each of the five points above mentioned has been taken and cross-checked against the others and compared with the bacteriological findings and the results. Most of these calculations led up "blind alleys" and are too inconclusive to produce.

In the case of *history*, the figures are as shown in Table II. :—

TABLE II.

—	All cases.	—	Subac. rhm. group.	Infec. C. group.
		Per cent.		
Related (+ +) ..	63	31·5	54	26
Positive (+) ..	75	37·5	20	38
Negative (0) ..	62	31·0	26	36

I have been unable to discover any relation between the history of tonsils and their size, the condition of the crypts, or enlargement of glands. The bacterial findings showed that *Streptococcus hæmolyticus* occurred in much greater proportion in the positive than in the related cases. The figures in the two right-hand columns support the recognised clinical fact that acute rheumatism is often preceded or accompanied by tonsillitis. Table III. shows the connexion between a related history and systemic disease from another angle.

TABLE III.

Systemic infection.	All cases.	Related history cases.
	Per cent.	
Subacute rheumatism ..	27	46
Infective C	45	36·5
,, D	14	8
Fibrositis	9·5	9·5

Table III. shows that a related history is commonest in the subacute rheumatism group. Table IV. shows—what does not necessarily follow—that this form of arthritis is commonest among the related history cases.

TABLE IV.—"*Result Percentages*"

Of whole series = 78 per cent. cured and improved.

—	History related.	History negative.
	Per cent.	
In all cases	91	64
In subacute rheumatism group ..	55	50
In infective C group	96	51

It will be seen that the related history cases show a high percentage (91) of good results. The results in the subacute rheumatism group as a whole are also good (93). I concluded at first that the 91 per cent. was due to the relatively large number of subacute

rheumatism cases with a related history. The above figures show that this is not so, the subacute rheumatism percentage being only 55 as against 96 for "infective C." The high percentage of good results in cases with a related history is therefore due to two factors—the larger number of cases of subacute rheumatism with 55 per cent., and a smaller number of cases of "infective C" with 96 per cent. This is an example of the ease with which figures can lead one astray. They show, which was not at first evident, that a related history in a case of infective (focal) arthritis is a particularly favourable point in prognosis when considering tonsillectomy; whereas in subacute rheumatism it is more often met with but does not mean quite so much.

Crypt Contents.—Pus and debris were noted in 156 cases; bleeding only, without pus, in 16. Of the 44 cases in which no pus was found on pressure, 27 cases showed pus in dilated crypts on section. The remaining 17 were fibrous tonsils containing a small amount of serous fluid only and were not heavily infected. These tonsils probably had no bearing on the case, were not really infected, and should not have been removed. In considering a tonsil pressure on which produces neither pus nor bleeding, the other points against it should be very definite before tonsillectomy is advised.

Enlarged Glands.—Table V. shows the incidence of palpably enlarged tonsillar lymphatic glands.

TABLE V.—*Glands.*

Type of case in which glands were enlarged.	Per cent.	Type of case in which glands were enlarged.	Per cent.
All cases	57·5	Related (+ +) history	61·0
Large tonsils	60·0	Negative history	58·0
Medium ,,	60·0	*S. hæmolyticus* infection	55·0
Small ,,	54·0	Subacute rheum. group	54·0
Tonsillar "remains"	60·0	Infective C group	60·0

It will be seen that these figures show very little variation. They afford an instance of the "blind alleys" referred to earlier and show that, although enlargement of these glands points to tonsillar infection, it is no indication of focal activity. It must be remembered that they may remain enlarged after a tonsil infection has subsided.

Table VI. shows the bacteriological findings. A streptococcus was isolated in 197 out of 200 cases—i.e., 98·5 per cent.

TABLE VI.—*Bacteriological Findings.*

Organism.	—	In pure culture.
	Per cent.	
Streptococcus hæmolyticus (pyogenes)	36·5	8
,, *viridans (salivarius)*	92·5	29
,, *non-hæmolyticus*	49·0	5
S. mucosus capsulatus	4·5	—
Micrococcus catarrhalis	2·5	—
Bacillus pfeifferi	1·0	—
Pneumococcus	0·5	—

There were only three non-streptococcal cases; two of them yielded *Staphylococcus albus* only and belonged to the infective arthritis D group. The third, a subacute rheumatism, gave *S. albus* and *aureus*.

In only one case, and then only on one side, was a sterile tonsil found.

The Part Played by Streptococcus viridans.

For comparison and control purposes 100 tonsils, removed from children of under 10 years, have been examined by the same technique. These tonsils were of the hypertrophied type and were selected as the nearest obtainable to the normal tonsil. Table VII. shows the bacteriology of these. A streptococcus was isolated in 72 per cent.

I think it is very curious that the pneumococcus was only found in one of my rheumatic cases, in view of its frequency in nasal infection. It suggests the possibility of transmutation. In the great majority of cases the infection was symmetrical. For calculation purposes the *Streptococcus viridans* was so ubiquitous as to preclude any useful comparison.

TABLE VII.—*Organisms in "Normal Tonsils."*

Organism.	—	In pure culture.
	Per cent.	
Streptococcus hæmolyticus	11	1
,, *viridans*	68	16
,, *non-hæmolyticus*	17	Nil
S. mucosus capsulatus	1	—
Micrococcus catarrhalis	21	—
Bacillus pfeifferi	6	—
Pneumococcus	10	—
Sterile	8	—
Staphylococcus albus only	5	—

I therefore took the *Streptococcus hæmolyticus* cases—36·5 per cent. Calculations show that this organism is not specially associated with pus or enlarged glands; it shows no predilection for subacute rheumatism (35 per cent.), or for infective arthritis C (42 per cent.). There was nothing to indicate any greater severity of the arthritis; and the results were only very slightly better than those for all cases—82 per cent. as against 78 per cent. The only fact that emerged was that which has been already stated under history—an occurrence in 42 per cent. of positive cases against only 22 per cent. in related cases. It appears to me probable that the *Streptococcus hæmolyticus* is associated with ordinary tonsillitis, acute or chronic, rather than with arthritis and the focal tonsil. I think that to this bacteriological class belong several patients whose arthritis has remained stationary or become worse, but who have clearly stated that their general health has considerably improved since the operation. It is significant that one case when first admitted had acute tonsillitis; culture of the pus from the crypt mouths produced *Streptococcus hæmolyticus*. A fortnight later the tonsils were removed and grew *Streptococcus viridans* only.

The 11 cases with neither *Streptococcus viridans* nor *Streptococcus hæmolyticus* show nothing characteristic.

There remains the problem of *Streptococcus viridans*, which is either an active agent in infective arthritis or is so common as to mean nothing. The evidence is in favour of the former; for, in brief, the *Streptococcus viridans* has been found associated with arthritis by many observers, has reproduced experimental arthritis in animals, and is a normal inhabitant of the mouth; its virulence is highly variable and, like other streptococci, and in their company, it probably leads a double life. It is accepted that a strain, at first harmless, may be made virulent by passage through animal tissues, and I am inclined to believe that the normal tonsil normally contains in its crypts the *Streptococcus viridans* in a quiescent state; that damage to the crypt epithelium occurs, that the organism meeting with a raw surface penetrates the tissues, becomes virulent, and, *given the proper conditions*—necessarily a wide term—produces substances sufficiently toxic to produce changes in joint and fibrous tissue, substances which are formed in proportion to the activity for the time being of the organism, and one of which is chemically neutralised by salicylates.

I think it must be admitted that the above analysis fails to show that a focally active tonsil possesses any peculiar characteristics by which it can be clinically identified.

Results of Tonsillectomy.

The results prove a little more illuminating. These numbers are based on accurate counts. They are derived from the signed statements of the patients

themselves, and in points of doubt I have not taken the benefit. The difficulty is one of interpretation. There are so many factors to be considered that only by cross-checking in every possible direction has it been possible to minimise the error of attributing success or failure to the wrong cause.

TABLE VIII.

Group.	Cured	Improved	Unchanged	Worse	Percentage cured and improved.
Subacute rheumatism	17	24	2	1	93
Infective arthritis C	14	56	8	7	82
" " D	1	9	4	6	50
Fibrositis	5	7	4	1	71
Neuritis	Nil	2	3	1	33⅓

In neuritis it is probable that the fibrous tissue survives the removal of the infective focus which caused it, ultimately contracts, and produces persisting pain by pressure. Tonsillectomy, therefore, can do little beyond preventing extension unless the disease is in its very early stages.

TABLE IX.—*Age as a Factor.*

—	Cured.	Improved.	Unchanged.	Worse.	Percentage cured and improved.
Up to 20 ..	12	23	2	2	89
Over 40 ..	2	27	2	5	80

As might be expected, results are better in younger patients. At the same time it is clear, from the figure of 80 per cent., that an age of 40 or over is no bar to a successful result.

TABLE X.

Age in years.		10 to 20.	21 to 30.	Average age— under : : over	31 to 40.	41 to 50.	51 to 60.	Over 60.
No. of cases	cured ..	12	16	28 : : 7	6	—	1	—
	worse ..	2	6	8 : : 9	4	1	3	1

In Table X. the proportion 28 : : 7 is exaggerated by the high percentage of good results in the subacute rheumatism patients, whose average age was low—25. These good results might appear to be due to this age factor, but are not so in reality. The improvement percentage of subacute rheumatism cases over 30 is still 91 per cent. Age, therefore, is not as important a factor as appears at first sight.

TABLE XI.—*Duration of the Systemic Disease.*

Duration.	Cured.	Improved.	Unchanged.	Worse.	Percentage cured and improved.
Under one year..	33	44	7	6	85
Over five years ..	2	22	5	4	73

Of the 35 cured cases in Table XI. the duration was less than a year in 33. This high ratio is exaggerated by the fact that in 51 per cent. of the whole series the duration was less than one year, the duration numbers being as follows:—

Under one year	102 cases.
One to five years	55 "
Over five years	43 "

A duration of more than one year in subacute rheumatism, and more than three in "infective C" was exceptional. Duration, however, does appear to be a factor in prognosis. The results show that a complete cure is unlikely if the arthritis has lasted more than 12 months; but that after five years 73 per cent. of cases are still capable of improvement. I consider that a long duration in a patient over 40 should make one very carefully balance the rest of the evidence before embarking on tonsillectomy.

TABLE XII.—*Percentages Cured and Improved under Various Categories.*

Category.	Per cent.	Category.	Per cent.
Subacute rheumatism—		*Streptococcus hæmolyticus*	
Under 30	94	cases	81
All cases	93	Enlarged glands	77
Related history cases ..	91	Duration more than five years	73
Aged 10 to 20	89	Fibrositis	71
Duration less than one year	85	Negative history cases..	64
Infective arthritis C—		Infective arthritis D ..	50
All cases	82	Neuritis..	33⅓
Under 30	82		

The importance of the figures in Table XII. must not be exaggerated. They represent a very small attack on the problem of chronic arthritis. During the time that these 200 patients were dealt with over 7000 cases of many and various forms of arthritis and allied conditions passed through the hospital. If, however, these results are better than those obtained without the aid of surgery they tend to confirm the focal infection theory. Possibly research into the histology of proved "focal" tonsils may reveal something of the barrier which stands between the system of one individual and an infection which, in another, results in such widespread tissue changes as are seen in chronic arthritis. S. J. Crowe,[1] working on these lines, has found ulcerated areas in the crypt epithelium of tonsils removed from patients with infectious arthritis (="infective arthritis" C).

Summary of Conclusions.

1. A probable tonsil focus can be found in a large number of cases of subacute rheumatism, chronic infective (focal) arthritis, and fibrositis.

2. When searching for a focus in the tonsils attention should be paid particularly to their history, size, colour, crypt contents, and to the associated lymphatic glands; and these points should be carefully balanced before deciding on tonsillectomy: (*a*) In an actively focal tonsil one or more of these points may be negative, but if all five are negative the tonsil should be assumed to be healthy. (*b*) The tonsil of chronic tonsillitis without systemic infection cannot be distinguished from the focal tonsil by physical signs or by present bacteriological methods, but only by inference.

3. In selecting cases for operation a history of tonsillitis associated with onset or recurrences is favourable in cases of infective (focal) arthritis, and to a lesser extent in subacute rheumatism, where such a history is commoner.

4. The younger the patient, and the shorter the duration of disease, the better the prospects, but within very wide limits neither age nor duration are a bar to success.

5. The bacteriological evidence, though insufficient to convict the *Streptococcus viridans* as the primary infective agent in chronic focal arthritis, increases the suspicion under which this organism already lies.

6. In the subacute rheumatism group the results are so good that the operation should become a routine part of the treatment, if only as a prophylactic against recurrences and later endocarditis.

7. In cases of chronic focal arthritis, if the balance of evidence, obtained as indicated in Conclusion 2, condemns the tonsils and they are completely excised, improvement may be expected in 80 per cent. of cases.

In conclusion, I have to express my gratitude for the help given me by my colleagues and others on the staff of the Royal Bath Hospital.

[1] Archives of Internal Medicine, April, 1924, xxxiii., 473–482.

PEMPHIGUS NEONATORUM.

By T. H. C. BENIANS, F.R.C.S. Eng.,
PATHOLOGIST TO THE PRINCE OF WALES'S AND NORTH MIDDLESEX HOSPITALS;
AND
BERTRAM H. JONES, M.D., M.R.C.P. Lond.

The synonyms of "pemphigus neonatorum" are impetigo contagiosa neonatorum, bullous impetigo of infants, Ritter's disease, pemphigus contagiosus, and impetigo contagiosa bullosa.

It is a rare but highly contagious disease of the skin occurring in the new-born, usually between the fourth and fourteenth day after birth. It is characterised by the development on various parts of the body of vesicles, bullæ, or blebs, which rupture readily, leaving moist, red, smooth, glistening defects in the uppermost layers of the epidermis, which, in cases that recover, heal without a scar. Two forms of the disease are usually distinguished:—

1. A *mild type* in which the skin lesions are not numerous and tend to dry up and heal more or less quickly, and in which there is freedom from systemic disturbance. In this type recovery occurs within a few weeks.
2. A *grave type* in which the skin eruptions continue to arise and to extend over large areas of the body and in which there are febrile and other systemic manifestations.[1]

The distribution, as recorded by Cole and Ruh,[2] is universal, cases having been reported in Europe, America, Japan, and Asia. It occurs sporadically and in localised epidemics.

Historical.

Pemphigus neonatorum was first described in France in 1773 by Ochène.[3] In England an epidemic occurred in 1834 and was described by Rigby [4]; several mothers contracted the disease from their children, and Rigby himself was infected. Ritter recorded epidemics occurring in a foundling hospital in Prague between 1878 and 1880, with a mortality of 48 per cent. In 1886 Demme [5] studied the bacteriology, and isolated and cultivated a non-chromogenic diplococcus. In 1891 Almquist [6] described in the serum from a vesicle a diplococcus which on culture resembled the *Staphylococcus aureus*. This organism, on inoculation on the human skin, was found to produce a vesicular eruption, and in this way differed from the typical *S. aureus*, which commonly produces a follicular infection. Therefore Almquist suggested that the organism should be called *Micrococcus pemphigi neonatorum*. In 1900 Matzenaur [7] concluded that pemphigus neonatorum and impetigo contagiosa were due to the *S. aureus*, and that they were identical diseases. Some confusion has arisen from the fact that in the same year Sabouraud [8] came to the conclusion that the impetigo of Tilbury Fox (impetigo contagiosa of children and adults) was due to a primary infection with streptococci. Sabouraud found that if the blister contents were cultured in ascitic fluid a streptococcus grew after 48 hours' incubation, and that in equal quantities of broth and ascitic fluid, incubated for 24 hours, the cultures contained a mixture of streptococci and staphylococci, while if broth alone was used as the culture medium, and incubated for 12 hours, the fluid contained a few streptococci and numerous staphylococci. In 1903 Whitfield [9] described a case in which the date of onset was the seventeenth day after birth; two days later the mother developed a typical lesion on the hand. Cultures from the contents of a vesicle in a capillary tube of ascitic fluid, as described by McLeod,[10] produced a pure growth of streptococci from the child and of streptococci and *S. aureus* from the mother. It is to be noticed that Sabouraud was dealing with the impetigo contagiosa of Tilbury Fox, and that in Whitfield's case the date of onset was unusually late (17 days), so that he may have been describing a similar condition in an infant. We think these cases of streptococcus infection are to be distinguished from those of true impetigo contagiosa of the new-born.

In 1903 Maguire [11] described an epidemic of 18 cases, with a fatal result in eight; all the cases but one had come into contact with a nurse suffering from "pustular acne." In many instances infection was spread to other members of the family when the patient arrived home, producing in some typical bullæ. He states that in all the fatal cases the umbilicus became infected during the course of the disease. In the two cases investigated *S. aureus* was isolated. In 1906 Clegg and Wherry,[12] examining an epidemic at Manilla, agreed with Almquist that the coccus isolated closely resembled *S. aureus* on culture medium, but differed from it in that litmus milk was coagulated in a week and that no indol was produced in broth. The diplococcal arrangement could be reproduced in milk and serum-broth cultures. Experiments in animals failed to produce any typical lesions, but auto-inoculation produced a typical bulla in 30 hours; the organism, however, was not recovered from the lesion, which healed in 48 hours. In 1914 Cole and Ruh [2] described a series of eight cases, and grew *S. aureus* in pure culture in each. In 1917 F. H. Falls [13] described his very complete investigations on a series of 69 cases which occurred at Chicago in 1915 and 1916, and concluded that the disease was caused by infection with *S. aureus*, and that this differed from other staphylococcal infections in that the organism produced vesicular eruptions on inoculation into man, and also that in certain liquid media it appeared as a diplococcus which formed short chains. A staphylococcus is also cited as the causative agent by a number of continental writers in recent years: Weiland 1922,[14] Shultheiss 1923,[15] Stern 1927,[16] and Richter 1927.[17] In 1925 Millon, Caldwell, and Winians [18] described an outbreak in which the infecting agent was a *S. aureus*, derived, they considered, from the mother's milk. We have investigated the matter, and have concluded that this is an unlikely and unusual method of infection.

Cases Examined by the Present Writers.

We have had the opportunity of observing two epidemics and one further isolated case in the lying-in wards of a general hospital, and two cases at a lying-in hospital; these institutions will be referred to as hospitals A and B respectively. In March and April, 1927, an epidemic of 18 cases occurred in the maternity wards of hospital A. The average age at onset was six or seven days, the youngest infant being 4 days old and the eldest 12 days. The eruption began on the head, face, or chin in 11 cases, and in the other cases appeared first on the fingers, arms, wrists, axillæ, shoulders, neck, legs, or toes. In all cases where fluid could be obtained from an unbroken vesicle *S. aureus* was grown in pure culture and no other organism was obtained. The interval between the cases varied from one to nine days. As soon as the diagnosis was certain the mother and child were isolated from the other maternity patients. During this time a nurse attending the babies was found to be suffering from "a series of boils," and when she left the ward the epidemic ended.

In July, 1927, there was a small epidemic of four cases. The age of the babies at the onset varied from 5 to 16 days, the eruption broke out on the fingers in two cases, the neck and head in one case, and the toes in one case. From all vesicles examined *S. aureus* was grown in pure culture. The interval between the cases varied from one to ten days. In this outbreak no primary source of infection could be found, and we therefore proceeded to make observations as to the occurrence of *S. aureus* in the normal child and mother. (These will be referred to later.) A few days after the first case was transferred to the isolation ward the nurse under whose care it had now come developed a vesicular eruption on her knuckles from which a *S. aureus* was isolated.

In January, 1928, a solitary case occurred at hospital A. The child was 10 days old at the time

of onset, and had the typical bullous eruption on the fingers of the left hand, the back of the neck, and just external to the nostril. A pure culture of *S. aureus* was obtained from the blister fluid. The mother was then found to be suffering from a perionychial infection of the bullous type, which she had first noticed four days before the onset of the eruption on the child. The mother's lesion was cultured when the child was first seen, at which time it was in the stage of recovery, and *S. albus* was found in pure culture.

In February, 1928, we were fortunate enough to have permission to examine two cases which occurred in hospital B. Both began on the same day, in infants 4 days old. One child had a lesion on the right thigh and the other a lesion on the right shoulder. When first examined by us the vesicles had already ruptured and had been covered by a weak mercurial ointment; a culture was taken, however, by raising up the edge of the broken bulla, and in each case *S. aureus* was obtained in pure culture. We think it probable that these infants were infected by the nurse who had attended them on the day of birth, for on the following day she reported that she had for a day or two noticed a small pustular vesicle on the hand. She was sent off duty, and while off duty a week later a similar vesicle occurred on another finger. In all these cases constitutional symptoms were absent, except in two cases with extensive exfoliation, and the umbilical scar was unaffected.

Our cases show a probable source of origin of the first epidemic in a nurse with "boils," after whose departure the epidemic ceased; this was a temporary nurse from outside the institution, and no accurate note of the nature of the lesion was made. In the second epidemic no original cause was found, but the infection of a nurse from a baby occurred. In the third a pre-existing vesicular eruption was present in the mother. In the fourth a nurse with staphylococcal vesicles of the hand was considered to be the cause. The direct contagiousness to and from adults, and the fact that, in nearly every case, the vesicular infection remains true to type is well illustrated.

Bacteriology of the Epidemics.

We found no streptococci and no infecting agent except *S. aureus*. We examined blisters in their very early stages and found organisms present in considerable numbers; whilst many of these were in diplococcal rather than in staphylococcal form, we have not found, either in films or cultures, anything that could properly be called a streptococcus. In cultures, more especially perhaps on serum-containing fluids, the cocci may take up a chain form of three or four members, but this is also found in cultures of *S. aureus* from any active lesion. On solid medium, such as serum-agar, the staphylococcal arrangement once more becomes apparent. The relative lack of pathogenicity of the organisms when injected into mice shows the character of a staphylococcus rather than a streptococcus, and this we found whether we injected the blister fluid itself or the cocci grown from it.

The *S. aureus* isolated in some five cases was fully tested and found to be hæmolytic; it acidified milk but without clotting, and no indol was produced in peptone water. In these and in the sugar reactions we found no fixed differentiating character from the ordinary *S. aureus* isolated from boils and carbuncles, cultures from two of which were examined in parallel with those from the pemphigus blisters as controls. The staphylococcus characteristic of pemphigus neonatorum differs from that commonly isolated from boils and other follicular infections of the skin in that it produces vesicular lesions, not only in the new-born child but also in those cases in which we have been able to trace the passage from a child to an adult.

In three cases fluid from blisters was inoculated direct into a mouse subcutaneously; it had no lethal effect, and streptococci were not found in the blood stream.

Examination for a Filterable Virus.

We have also sought for a filterable virus which might be acting as a primary infecting agent or as an adjuvant to the cocci. Fresh fluid from the blisters was injected intradermically into the footpads of guinea-pigs and mice (five cases). In these circumstances the relatively small numbers of staphylococci present have no harmful effect, whereas if a filterable virus were present we might expect a herpetiform eruption. Our results were entirely negative. As a contrast we examined one child of 6 months with a typically bullous eruption, and on culture of the blister-fluid both streptococci and staphylococci were grown in ascitic fluid media. We concluded that the patient was suffering from the impetigo of Tilbury Fox, thus confirming the work of Sabouraud and Whitfield, and further differentiating the ætiology of pemphigus neonatorum from that condition.

Types of Outbreak.

The epidemics we have traced in the literature seem to fall into three classes:—

1. Those of a violent and rapidly spreading type like those described by Rigby[4] and Ritter. In these instances one must presume that there has been a direct transmission of the virus from case to case. This direct transfer makes both for rapidity of spread and, by "passage" of the organism, for increased virulence and higher mortality.

2. Epidemics such as that described by Schultheiss,[15] in which a large number of cases were infected from the same source in a short space of time. The sudden widespread nature of the epidemic in this instance led to the implication of the institution laundry, and it was found that the clean linen was being sorted by a person with a suppurating perionychia.

3. The common type of epidemic, such as that with which we have had to deal, and which consists usually in a series of mild cases. In these we suspect some constant carrier of infection, but have not always succeeded in identifying it.

Schultheiss [15] refers to cases of infantile conjunctivitis during the epidemic. We have noted the same thing, both during the epidemic and also during periods when the wards were entirely free from pemphigus. Cultures from most of these cases grew *S. aureus* only, and it seems probable that this infection is closely allied to pemphigus neonatorum.

Mortality.

The mortality in the earlier epidemics described by Ritter and Maguire was 48 per cent., but recently it has been very much less, and in our own series there were no fatal cases. It has been repeatedly found that involvement of the umbilicus, with its large, recently clotted vessels, is likely to lead to pyæmia and death. Undoubtedly the low mortality in recent epidemics is related to the immediate isolation of infected cases and to the modern aseptic treatment of the umbilical scar.

Spread of Infection.

Wherever in our cases we have been able to trace the conveyance of infection either from the adult to the baby or vice versa the infection has been, with one doubtful exception, of a pemphigoid character. We therefore think it probable that a lesion of pemphigoid type, whether in an adult or infant, is much more likely to arise by infection from a similar blister lesion than from the ordinary follicular type of staphylococcal infection. If the staphylococcus is, as we believe, the cause of the infection we must look for direct contagion by transfer from case to case or from parent or attendant. In addition to direct contact infection Schultheiss's epidemic shows a conveyance by fomites (i.e., linen).

Auto-infection.—The possibility that the infective organism is present on the skin and causes an infection as a secondary effect of some constitutional condition cannot be overlooked. We see instances of this sort in certain trophic and toxic conditions, for instance herpetic eruption or the pustule of

small-pox, in which the staphylococci take root in the cutaneous tissues, apparently as a result of a central infection by some other virus. *S. aureus* may be found on the normal baby, but our own experimental work and that of Falls does not support the thesis of an infection arising spontaneously in this way, nor of a primary infecting factor which might let in *S. aureus* as a secondary invader. Dr. Gregorson in a recent article [19] speaks of a toxic neuritis in certain motor nerves, but it is difficult to see how this could be related to cutaneous infections, nor have we noted the constitutional enfeeblement to which he refers in either mother or child.

Possible Sources of Infection.—We have shown one source of infection in some of our cases to be specific blister infections of the skin due to staphylococci, but in other cases and in some reported epidemics no such source has been demonstrated. We therefore decided to investigate the occurrence of *S. aureus* in the milk and throats of mothers in the antenatal and puerperal states, and also to investigate the incidence of this organism on the recently born healthy infant. We found in the antenatal clinic (attached to hospital A) that *S. aureus* occurred in 12 per cent. of throat swabs from 66 patients. An examination of the breast secretion in 34 cases showed that the *S. aureus* occurred in one case only, or 3 per cent.; 36 per cent. were found to contain *S. albus* and 60 per cent. were sterile. In the puerperium 83 throat swabs were cultured, and of these 15 per cent. contained *S. aureus*. In 58 cases in which we cultured the milk 17 per cent. contained *S. aureus*. We then investigated 25 normal babies from 4 hours old to 9 days old; in each case a swab from the nose, the skin, and the umbilical cord or scar was cultured. The outstanding feature of this investigation was the frequent presence of *sarcina lutea* in all the situations examined. *S. aureus* was found twice in the nares and three times in the umbilical scar, but in no case on the ordinary skin surface. In the three cases where *S. aureus* was found on the child the mothers were investigated also, but no coccus was grown from either throat or milk. From this investigation we concluded that the bacteriology of the infant's skin, nose, and cord has no close relationship to that of the mother's milk or throat.

In the last three cases of impetigo neonatorum investigated we carried out bacteriological examinations of the mother's milk and throat and found that the *S. aureus* was not present in either; moreover, this organism was not found on the children's skin apart from the lesion, nor about the umbilicus or nares. In these three cases a definite source of infection was found elsewhere; in the first case the mother had a perionychial vesicular infection, and both the last two cases were attended on the day of birth by a woman with an infected vesicle on her finger.

S. aureus, therefore, may be carried in what appears to be a harmless form on various regions of the body in both adults and babies. It is fairly common in the throats of quite healthy people. We have found it in the colostrum of pregnant women some weeks before delivery and in the milk after delivery; if there is any congestion of the breast it is fairly often present. The organism found in most instances presents the cultural and biochemical characters of *S. aureus* as isolated from suppurating lesions such as boils or pemphigus blisters. In addition to these sources among apparently healthy people it is certain, from the frequency of mild infections of staphylococcal type such as blepharitis and small cutaneous pustules, that new-born babies must frequently come in contact with this infecting agent. In spite of this the disease remains comparatively rare, and it seems probable that the ordinary cutaneous pyogenic infection is at any rate less likely to lead to pemphigus in contacts than is a specific type of blister lesion.

In all the routine biochemical tests we have not found the staphylococcus of pemphigus neonatorum to differ from that of follicular abscesses, and in this our findings for the most part confirm those of other workers.

Conclusions.

(*a*) Pemphigus neonatorum is due to a primary infection with a *S. aureus*—i.e., one indistinguishable biochemically and culturally from the *S. pyogenes aureus*.

(*b*) In most cases the primary source of infection can be traced to a septic focus on the mother or on one of the attendants who come directly or indirectly in contact with the infant. In our cases the septic focus was in nearly every case of the blister type and we consider that probably this type of lesion is much more apt to lead to pemphigus infection than the commoner types of staphylococcal lesion such as follicular abscesses.

(*c*) *S. aureus* is frequently found in the throat and milk of mothers before and after childbirth, but this cannot be considered the usual primary source of infection.

(*d*) In fatal cases it is found that the umbilicus has usually become inflamed and it should therefore always be kept as clean as possible.

(*e*) Our experiments, although limited in number, do not support the thesis of a filterable virus.

Our conclusions differ slightly from those set out in the Ministry of Health Memorandum, in that we believe the staphylococcus to be the sole cause of the infection. We further think that conveyance of the infection is usually from a blister type of lesion—that is to say, from a superficial infection of the skin including, for instance, an infective eczema. We also think that the staphylococcal conjunctivitis sometimes seen in the new-born may be an allied condition.

Suggested Measures During an Outbreak.

Infected cases should be isolated.

Bed, bedding, &c., should be sterilised, but burning it should be entirely unnecessary.

All other infants should be carefully examined for possible early stages of infection, and for allied infections such as conjunctivitis.

The mother and attendants should be examined for septic conditions and the laundry staff for possible infection, including any recent history of cutaneous infection, especially of the bullous type. In this inquiry the wholehearted coöperation of the nursing staff must be carefully sought. It is very important that they should not, as so often happens, get the wrong impression and be made to feel that there is any imputation against their skill or cleanliness.

If the epidemic continues it might be well to cease bathing all new-born babies and substitute rubbing the skin with sterile oil.

In all cases of pemphigus neonatorum particular attention should be paid to keeping the umbilicus healthy, and it should be dressed, apart from the general toilet, with a dilute mercurial ointment, as a prophylactic measure.

Our thanks are due to Dr. E. I. Clark for help with the bacteriological work of this investigation.

A STUDY OF 'ASSIVE IMMUNISATION IN SCARLET FEVER.

By ALEXANDER JOE, D.S.C., M.D. Edin.,
:DICAL SUPERINTENDENT, NORTH-WESTERN HOSPITAL, LONDON;
AND
R. SWYER, M.R.C.S. Eng., D.P.H.,
SENIOR ASSISTANT MEDICAL OFFICER TO THE HOSPITAL.

Any procedure which will cut short an outbreak of fectious disease must be regarded from all points view as of very great value. Its value to the ntact cannot be over-estimated, for by its means he ay escape an attack of the disease and the consequent ssible risk to life and well-being, certain loss of time, d in many cases financial loss. Also it is obvious at when the outbreak occurs in hospital and when iarantine has to be observed a certain proportion of e contacts are bound to be detained for a longer or orter period after they are fit to return home. ıould a secondary case arise this period must, of urse, be lengthened by another quarantine period id, considering the problem from the standpoint of spital administration, any method of obviating or ducing quarantine periods must result in a consider- le saving of patients' accommodation and expense. a clinical investigation of the new work on scarlet ver [1] one of us demonstrated that a passive ımunity to scarlet fever could be brought about by e injection of scarlet fever antitoxic serum, and it as to make a detailed study of this phenomenon and test its practical possibilities in the limitation of itbreaks of scarlet fever in the non-scarlet fever ards of an infectious diseases hospital that the llowing work was carried out. Our study has tended over a period of two years; observations ıve been made in 40 separate outbreaks of scarlet ver and include the immunisation records of over 50 individuals. Other workers have employed the ethod, particularly in children's [2] and infectious spitals [3 4 5 6] throughout the country, and it ppears to have been successful both when the ımunity was estimated by the Dick test and when was assessed in terms of actual resistance to the sease.[4 7] The dosage now generally recommended from 2·5 to 5 c.cm. of the concentrated antiserum, it, as James [8] has pointed out, comparatively little ork has been published in this country on the amount antitoxin necessary to secure protection. As a sult of his investigation he came to the conclusion at 5 c.cm. is usually sufficient to protect susceptible ntacts for a minimum period of seven days, but that rtain highly susceptible individuals giving a strongly sitive Dick reaction probably required 10 c.cm. uickshank [9] has also worked at this problem and ates that in general 2·5 c.cm. of a concentrated ıtitoxin protects for three to six days, 5 c.cm. for ven to ten days, and 10 c.cm. for two or three eeks, and in another paper [10] he indicates that the ımediate protection afforded by different doses of e antitoxin does not vary very much, but that the ief effect of increasing the dose is to bring about a ore lasting immunity.

Methods.

On the occurrence of a case of scarlet fever in a non-scarlet ard the cross-infected case was promptly isolated and search ade for a probable infecting case. One of two measures as then adopted, attempts being made to limit the outbreak ther by quarantining the ward or by protecting the exposed sceptibles, after which quarantine was removed. As far possible these measures were used alternately, so that e results of the passive immunity experiments were ntrolled by those in which quarantine was observed. nce all the wards in which scarlet fever appeared contained ı average number of 20 beds, the total numbers exposed ould be comparable. In the passive immunity experiments l contacts were Dick-tested immediately, the results being rutinised after 24 hours and classified as follows: Reac- ons under 10 mm. in diameter Class I., from 10–20 mm. ass II., from 20–30 mm. Class III., and above 30 mm. Class IV. Following the practice of other observers, we have for practical purposes regarded Class I. reactors as immune. The susceptibles were then given their injections of scarlet fever antitoxin by the subcutaneous or intramuscular route, and were re-tested at an interval of 24 or 48 hours and at weekly intervals until they became positive again or were discharged from hospital. The toxin used in the testing was supplied by Dr. Hartley, of the Medical Research Institute. We were conversant with its properties and we have proved it over a long series of comparative tests to be exactly comparable with the Dick reagent used extensively in this country. The antitoxin was the ordinary commercial preparation put on the market by two well-known firms.

Immediate Results of Various Doses of Antitoxin.

In an attempt to decide upon the optimum dosage sufficient for immediate and complete protection we have employed injections of 3 c.cm. in 57 cases, 4 c.cm. in 41 cases, 5 c.cm. in 120 cases, and 10 c.cm. in 43 cases. On re-testing we found that after a 3 c.cm. dose 51 individuals (89·4 per cent.) became Dick-negative; after 4 c.cm. 40 (97·5 per cent.) became Dick-negative; after 5 c.cm. 101 (84·1 per cent.) became Dick-negative; and after 10 c.cm. 41 (95·3 per cent.) became Dick-negative.

These results raise some very interesting practical questions. For instance, it is a matter of considerable importance to find in a significant series of cases that 5 c.cm., which has come to be widely recommended as a suitable dose for the purpose, fails to confer passive immunity in 16 per cent. of cases, and that even by doubling this dose we cannot be sure of conferring a passive immunity on every case. It is also interesting to find that 3 c.cm. and 4 c.cm. doses seem to be as effective as the larger amounts. In considering these results as a whole, three factors occur to us as requiring attention. These are the possible variation of antitoxic content of various batches of serum, the question of age, and the state of susceptibility of the patient. Examination of the individual results in the various groups of patients immunised at any single time shows that no great variation in antitoxic content in the various batches could be detected. The 5 c.cm. series, the largest, was composed of 11 groups, each consisting of from 8 to 15 susceptibles. Only in three of these did we obtain a complete group immunity after protection, whereas in the remainder, according to the smaller or larger numbers comprised in the group, there were one, two, or three failures, and in no experiment were the unsuccessful cases concentrated in any single group. The same fact emerges from an analysis of group results in the other series. The question of age has also been examined; in the 5 c.cm. group there were seven failures to protect among 57 children under the age of 5, or 12·2 per cent. In the age-group 5–10, consisting of 47 children, there were 13 failures, or 27·6 per cent., and in the age-group 10–15 there were 5 failures out of 12, or 41·6 per cent. In spite of the fact that this important point is not brought out in either of the series immunised with 3 c.cm. or 4 c.cm.—all the failures in these being scattered indiscriminately throughout the age-periods under 5—we are inclined to attach importance to the suggestion implied in the analysis of the larger numbers, and feel that in considering dosage regard should be paid to age. The question of susceptibility also requires attention, and we have been able by grading our reactions to correlate this factor with the results of passive immunisation. In the 5 c.cm. series we find that this dose failed in 7 out of 16 Class IV. reactors (43·7 per cent.), in 9 out of 52 Class III. reactors (17·3 per cent.), and in 7 out of 52 Class II. reactors (13·4 per cent.). Unfortunately the Dick reactions were not graded in the 4 c.cm. series, but most of the 3 c.cm. series and all of the 10 c.cm. were graded, and an analysis of these brings out the same point. Our failures may partially be ascribed, therefore, to the high susceptibility, as shown by the Dick test, of a proportion of the patients. From a study of our records we find that after intramuscular inoculation of the protective dose 6 per cent., and after subcutaneous injection 11 per cent. of positive

Dick re-tests at a 24-hours' interval subsequently became negative, whereas after a 48-hour re-test further change in the reaction was unlikely. We are therefore inclined to recommend the intramuscular route to secure as rapid absorption as possible, and that a 48-hour interval be observed before re-testing to estimate the effect of immunisation.

Duration of Passive Immunity.

This is a matter of some importance and, on the analogy of other infections in which it is possible to produce this type of protection, we should not expect it to be of long duration. It is generally considered that, to be of value, passive immunity in scarlet fever should at least endure beyond the limit of the incubation period—i.e., for 7–10 days. On consulting the table it can be seen how far that demand is satisfied by different doses. For various reasons we were not able to follow up all our cases until they returned to their original positive reaction, but in each series of cases we think we have been able to follow up a sufficient number as far as the end of the second week to supply a satisfactory figure on which to calculate the probable number of negatives if all had been re-tested, and thereby establish a percentage in which the probable error is not great. Again the results vary with such irregularity that it is difficult to draw conclusions. We find that at the end of the first week, after a 3 c.cm. dose 75·4 per cent., and after a 4 c.cm. dose 92·6 per cent. are still negative, but after a 5 c.cm. dose only a little over half, 56·6 per cent., have not relapsed to the state of susceptibility. At the end of the second week there is a further falling off

Table showing Incidence and Duration of Passive Immunity after Various Doses of Scarlet Fever Antitoxin.

* Prob. neg. = Probable number of negatives if all surviving negatives from previous re-test had again been re-tested.

in the numbers, the 3 c.cm. and 4 c.cm. series now showing 47·3 and 58·5 per cent. respectively of negatives, whilst the 5 c.cm. series give a smaller percentage still—viz., 39·1. Again, the 10 c.cm. results are the most satisfactory since, although the percentage of negative results immediately after immunisation is not so high as obtained with the 4 c.cm. dosage, 93·0 and 83·7 per cent. of negatives at the end of the first and second weeks respectively may be regarded as satisfactory. This result also confirms the observation of Cruickshank that increasing the dosage for passive immunity in scarlet fever tends rather to prolong the duration of protection than to give a great increase in the number of negative reactions. It may be fair to attribute the better results obtained in the 3 c.cm. and 4 c.cm. series, when compared with the 5 c.cm. series, to the smaller total numbers involved, and if we do so, then we must regard the 10 c.cm. series as the only satisfactory one from the point of view of persistence.

During the course of the investigation eight case previously passively immunised subsequently deve loped scarlet fever, and, since these have a direc bearing on the protective value of the process an also on the duration of the immunity, details ar appended :—

CASE 1, aged 5. Exposed on Feb. 9th, 1928, and foun Dick-positive. On the 10th given 5 c.cm. antitoxin. O the 12th was still Dick-positive and developed scarlet feve on that date—i.e., two days after immunising injection.

CASE 2, aged 6. Exposed Feb. 6th, 1928, and found Dick positive. On the 10th given 5 c.cm. antitoxin. On the 12t was Dick-negative and developed scarlet fever on that dat —i.e., two days after immunising injection.

CASE 3, aged 10. On Oct. 27th, 1927, was Dick-positive Exposed Nov. 16th. On the 17th given 5 c.cm. antitoxin On the 18th was Dick-positive and on Nov. 21st took scarle fever—i.e., four days after immunising injection.

CASE 4, aged 15. Exposed Dec. 13th, 1926, and foun Dick-positive. On the 14th 3 c.cm. antitoxin. On th 15th and 21st was Dick-negative. On the 24th was Dick positive and took scarlet fever—i.e., ten days after immunisin injection.

CASE 5, aged 3. On March 24th, 1927, was Dick-positive Exposed April 14th. On the 15th given 4 c.cm. antitoxin Was Dick-negative on the 16th and 21st, but Dick-positiv on the 28th. On May 3rd took scarlet fever—i.e., 19 day after immunising dose.

CASE 6, aged 8. On July 20th, 1927, was Dick-positive Exposed on the 22nd. On the 23rd given 5 c.cm. antitoxin August 1st was Dick-negative, but found Dick-positive o the 8th. On the 12th took scarlet fever—i.e., 20 days afte immunising dose.

CASE 7, aged 2. Exposed April 15th, 1928, and foun Dick-positive. On the 16th given 5 c.cm. antitoxin. On th 18th was Dick-negative, but on the 25th and May 2nd wa Dick-positive. On the 9th took scarlet fever—i.e., 23 day after immunising dose.

CASE 8, aged 7. On Oct. 27th, 1927, was Dick-positive Exposed on Nov. 16th. On the 17th given 5 c.cm. antitoxin On the 18th was Dick-negative, but on the 25th and Dec. 2nd was Dick-positive. On the 15th took scarlet fever—i.e. 28 days after immunising dose.

It is interesting to note from these cases that in al except the second the presence or absence of immunity was correctly indicated by the Dick test. It is difficult to explain Case 2, except on the ground that it probably falls into the varying percentage of cases of scarlet fever which practically all workers have found to be Dick-negative even in the earliest stages of the disease. We suggest that the first three cases were incubating scarlet fever at the time of immunisation, and that the protective injection of 5 c.cm. of antitoxin did not succeed in blocking the onset and apparently failed to have much effect in modifying the incubation period, assuming that all three were the direct consequence of their respective primary infecting cases. All cases, however, were mild and without complications. Whatever the explanation, their occurrence seems to point to the necessity for a serum which in reasonably small doses will confer a more certain immunity. The remainder of the cases serve to emphasise the fact that, while passive immunisation may carry the susceptible contact over the immediate dangers of an exposure, it is transient and fails to protect against subsequent exposures at as short a space of time as three or four weeks after the first.

Comparison of Quarantine and Immunisation Methods.

In 21 of the 40 outbreaks studied the usual methods of quarantine for ten days were carried out. Of these 11 ended without further cases developing within the quarantine period, but in ten instances secondary cases appeared, resulting in the infection of 13 individuals. In the 19 outbreaks dealt with by passive immunisation 17 were free from the occurrence of subsequent cases within ten days of the appearance of the primary case. In two outbreaks, however, secondary cases did appear. These numbered three, one outbreak being responsible for Cases 1 and 2 detailed above, and another for Case 3. These figures give a clear indication of the protective value of passive immunisation and constitute a strong argument

its favour. Perhaps less important than the actual revention of cases of scarlet fever, but nevertheless of nsiderable moment to those responsible for hospital dministration, is the saving in accommodation. By ducing the period of quarantine from ten to three ays, the time occupied by testing and immunising, ere was a clear saving of seven days in each of 9 outbreaks, or a total of 133 days—i.e., roughly ur and a half months in two years. If the quarantined outbreaks had been immunised as well we should ave been able to double that gain, so that the uivalent accommodation of one ward for four and half months in one year would have been set free.

Serum Reactions.

Since the majority of our scarlet fever cross-infections curred amongst diphtheria patients who had been nsitised to horse serum, it was inevitable that there ould be a fairly heavy incidence of serum reactions. or the same reason it was often quite impossible to etermine whether to attribute any given rash to the erapeutic diphtheria antitoxin or the scarlet fever ophylactic, and we cannot offer any statistical vidence on this point. When patients had received phtheria antitoxin more than ten days previously ey were desensitised by an injection of 0·5 c.cm. of rmal horse serum. Serum sickness was confined to cal reactions and generalised urticarial rashes, and, hile inconvenient, the symptoms were transient and o serious effects were produced.

Discussion.

This phase of development of the recent work on carlet fever has not by any means reached finality. We had hoped to be able to outline a plan which ould be adapted to any outbreak and which, volving no more trouble than a preliminary Dick st followed by the immunising dose, could be relied pon to give a solid immunity of a reasonable duration. xperiment has shown that the problem of passively mmunising the susceptibles in an exposed ward-opulation cannot yet be reduced to these terms, and seems to us that the chief part of the difficulty is ue to the fact that we are working with a relatively eak antibody. This is apart from the handicap posed by the fact that no method of standardisation as yet been evolved which can provide us with n exact measure of the antitoxic content. In spite these limitations we think the case for passive mmunisation is strong. It is true that the present pe of scarlet fever is mild, but in the past we have en death resulting from scarlet fever complicating her acute infections and also such operations as that r cleft palate. If we add the administrative advanges in the saving of hospital accommodation, and conomic advantages to adult patients in the avoidance loss of working-time, we consider that this procedure rovides an opportunity which no one can afford to ismiss.

The results in attempts to limit outbreaks of scarlet ver by passive immunisation are encouraging, but mplete efficiency requires the introduction of an ntiserum comparable in potency with that of phtheria antitoxin. At present we suggest that sceptible contacts up to the age of ten years giving Dick reaction of less than 30 mm. diameter should ceive 5 c.cm. antitoxin intramuscularly and should e Dick-tested again after 48 hours, the dose to be peated in positive reactors. Contacts over 10 years age and those of any age giving a reaction of) mm. or over should receive an initial dose of) c.cm.

OBSERVATIONS ON THE SEDIMENTATION RATE IN PULMONARY TUBERCULOSIS.

BY R. R. TRAIL, M.D. ABERD., M.R.C.P. LOND.,
MEDICAL SUPERINTENDENT, KING EDWARD VII. SANATORIUM, MIDHURST;
AND
DORIS M. STONE, M.D., D.P.H. LOND.,
PATHOLOGIST TO THE SANATORIUM.

IN November, 1926, we began an investigation to determine the value of the sedimentation rate in the diagnosis and prognosis of pulmonary tuberculosis. The method adopted was that used by the late Dr. Arthur Inman, of Brompton Hospital, which differs from the usual methods in that very small amounts of blood are taken, permitting frequent examinations over long periods. Various methods of treatment were thus investigated—ordinary sanatorium routine, artificial pneumothorax, and sanocrysin.

Technique.

To two volumes of a sterile solution of 3·8 per cent. sodium citrate eight volumes of blood are added. The unit of volume is one drop of blood from a broad-ended glass pipette; the blood is drawn from an ear or finger and mixed in a watch-glass. A column of the diluted blood, 4 inches (=100 mm.) long, is drawn by capillary attraction into a fine glass tube about 6 inches long and of 2 mm. bore. The tube is sealed with sealing wax and placed vertically in a bed of plasticine. In this investigation the length of the clear fluid column above the sedimented red cells was measured at the end of an hour, in millimetres, this giving the result directly as a percentage. Any reading above 6 mm. for a man and 12 mm. for a woman is considered abnormal. In cases investigated over a long period the results were plotted in graph form (Fig. 1).

All cases entering the sanatorium were investigated a week after admission and at monthly intervals until discharged. Cases undergoing pneumothorax treatment were investigated once a week for the first month and afterwards every fortnight.

The Test in Diagnosis.

It has been proved by many investigators that the sedimentation test has little value in diagnosis and this agrees entirely with our findings. Of the 360 cases who entered the sanatorium during the period covered by the investigation 318 were clinically tuberculous, while in the remaining 42 no positive evidence was obtained. In these patients the changes in the sedimentation rate were as follows:—

A. *Clinically Tuberculous Cases.*

Sputum.	Sed. rate. Normal.	Sed. rate. Increased.	Total.
T.B. + ..	3	230	233
T.B. — ..	6	79	85
All cases	9	309	318

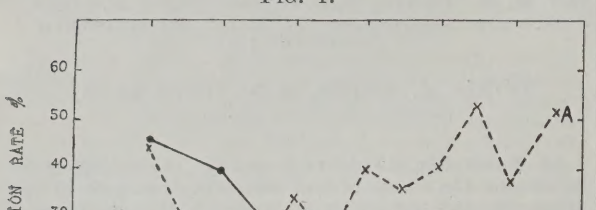
B. *Clinically Non-tuberculous Cases.*

—	Sed. rate. Normal.	Sed. rate. Increased.	Total.
Nil found ..	18	3	21
Other chest conditions..	8	7	15
Non-pulmonary conditions..	3	3	6
All cases ..	29	13	42

Thus, of 318 clinically tuberculous cases, 309, or 97 per cent., gave an increased sedimentation rate, while 9, or 3 per cent., gave a normal figure. Of the 42 clinically non-tuberculous cases, 29, or 69 per cent., gave a normal figure, while in 13, or 31 per cent., the rate was raised. These results indicate that, while an increased sedimentation rate may be used in conjunction with clinical findings to assist in the diagnosis of pulmonary tuberculosis, yet its usefulness in this respect is more than modified by the fact that other

chest conditions give a high percentage of positive results, while a definitely tuberculous case may give a normal figure; this is repeatedly demonstrated in cases after treatment. On the other hand, in its

FIG. 1.



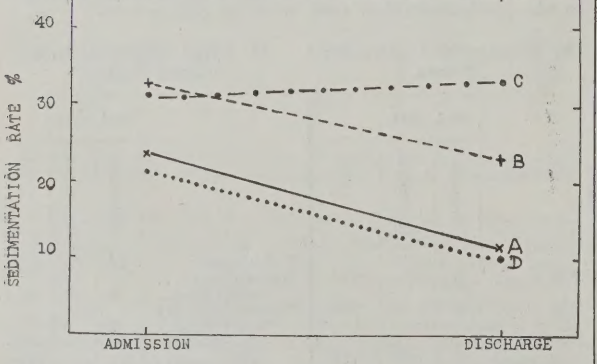
Illustrating cases (A) failing to respond to treatment, and (B) making satisfactory progress.

indication of response to treatment the test seems to have definite and unique value, and thereby to justify its use. Both in following up the progress of individual cases and in observing the results of treatment on patients as a whole a marked correlation has been found between the fluctuations in sedimentation rate and the clinical findings. This has been shown to hold good for all types of cases and treatments; the figures obtained bring out some interesting features.

Ordinary Sanatorium Routine.

One hundred cases, sputum "T.B. positive" on admission and under ordinary routine treatment only were observed over a period of not less than four months. On their clinical condition on discharge these patients fall into three classes: (A) Improved and arrested, with "T.B.—" sputum. (B) Improved but still with "T.B.+" sputum. (C) Stationary or worse. The average fall in sedimentation rate for the 100 patients was from 28 per cent. on admission to 22 per cent. on discharge, a definite but by no means striking improvement. The following graph illus-

FIG. 2.



trates, however, the difference in the degree of improvement according to the class of case (Fig. 2).

In Class A the fall in sedimentation rate (23 per cent.–12 per cent.) is very definite and practically reaches the normal on discharge; Class B shows an equally good fall in sedimentation rate (32 per cent. –22 per cent.), but begins and ends on a much higher level; Class C shows no improvement (31 per cent. –32 per cent.). A further graph, Class D, is added for comparison; it is based on 30 cases, "T.B. negative" on admission. This line is almost parallel with that of Class A.

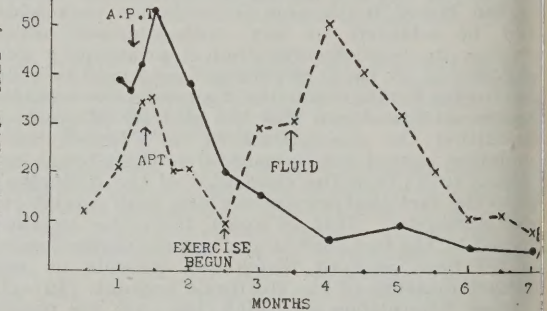
Isolated readings are useless owing to the rapi and striking reflection in the sedimentation rate such complications as dry pleurisy, onset of fluid i a pneumothorax case, mental shock, &c. Eve minor causes, such as worry, colds, falls, cauterisatio of the larynx, teeth extraction, &c., though they d not affect the temperature chart will temporaril upset the sedimentation readings. But, allowing fo these complications, if readings are taken at regula intervals the general trend of the sedimentation rat indicates clearly whether or not the progress of th patient is satisfactory. Fig. 1, which shows tw typical cases, might be multiplied indefinitely.

Special Treatment.

It is of the greatest interest to follow the change in the sedimentation rate in patients undergoin special treatment; this has been done most thoroughl in artificial pneumothorax cases. Typically in suc cases there follows a slight rise of varying intensity due perhaps to worry and shock, perhaps to sudde increase of auto-inoculation from the pushing dow of the diseased lung. This, in an uncomplicate case, generally precedes a steady fall to a norma level (Fig. 3 (A)).

The first exercise following the absolute res enjoined in the early stages in all cases of pneumo thorax treatment produces a slight rise in the sed

FIG. 3.



A.P.T. = artificial pneumothorax.

mentation rate, soon corrected and often repeate with increasing movement. As previously mentioned the onset and withdrawal of fluid invariably cause startling increase (Fig. 3 (B)). In one case a figure over 70 per cent. was reached with the onset of pleural effusion, but the patient left the sanatoriu with a normal sedimentation rate. The average fa in the sedimentation rate of the 20 pneumothora patients who have been induced and left the sana torium during the period under consideration is fro 31 per cent. to 14 per cent., a very satisfactor drop when it is realised that the majority of thes cases were tried first on routine treatment withou success.

Sanocrysin has been given to 11 patients who, afte improving, have hung fire and whose sputum ha remained "T.B. positive" in spite of at least fou months' treatment. As in pneumothorax patient the initial change in the sedimentation rate is definite rise followed, in satisfactory cases, by a fal The average fall of sedimentation rate in the case treated was from 20 per cent. to 10 per cent., figure which should be compared with those for Group I since the patients seemed likely to remain in thi category without special treatment. In six of th 11 cases the sputum became "T.B. negative" an remained so for a month before discharge, durin which time three examinations were made, while i several other patients improvement was obtained.

Cases under light treatment were also closel followed for a time, but no conclusive results hav been obtained.

Conclusions.

The simplified technique used in this investigation renders the test a simple and convenient aid in the summation of the individual case. The fallacies of the test as a diagnostic measure have been shown, but the prognostic significance of both the initial figure and its subsequent fluctuations is equally clear. Experience over the past two years has shown us the wisdom of a guarded prognosis in a pulmonary (not pleural) case, otherwise encouraging but with a high initial sedimentation rate—over 30 per cent.; nearly half these cases do not respond satisfactorily without special treatment. On the other hand, cases with a sedimentation rate of under 30 per cent. have a much more favourable outlook, and this appears to be independent of the initial presence or absence of bacilli in the sputum. The close relationship of the curves A and D in Fig. 2 is very striking. The changes in sedimentation rate during the first three months in the sanatorium indicate not only whether or not the patient is responding to treatment, but the rate at which this improvement is taking place and therefore the ultimate chance of recovery in the sanatorium. The figure obtained after four to five weeks' treatment is often as high as or a little higher than the initial figure; this happens repeatedly in patients whose progress is perfectly satisfactory and must therefore be discounted, but after this a rising sedimentation rate means lack of response and suggests the advisability of considering further treatment.

During pneumothorax treatment, after hæmoptysis, when giving gold, and in the initial stages of exercise, the sedimentation rate can be used to follow the progress minutely, and often indicates the onset of complications before these are otherwise apparent.

If the significance of its changes and their degree in the individual case can be accurately gauged, it appears to us that the test is of outstanding assistance to the clinician in his most difficult tasks—the evaluation of treatment and the formulation of prognosis.

Clinical and Laboratory Notes.

A CASE OF DISSECTING ANEURYSM OF THE AORTA.

BY C. VINCENT PATRICK, M.B. CAMB., F.R.C.S. ENG.,
LATE RESIDENT ASSISTANT SURGEON, ST. THOMAS'S HOSPITAL;
AND
JOHN F. TAYLOR, M.D. CAMB.,
LATE ASSISTANT PATHOLOGIST TO THE HOSPITAL.

THE following case seems worth recording on account of the rarity of the condition and of the difficulty in making a diagnosis.

A clerk, aged 32, was admitted to St. Thomas's Hospital on July 26th, 1928, complaining of difficulty in swallowing. He had been through the late war, but was never wounded and had never sustained any serious injury. He had, however, had cerebro-spinal fever in 1916, nephritis in 1917, and pneumonia in 1919. About June, 1925, he began to suffer from "indigestion," consisting chiefly of epigastric pain two hours after food. The pain was sometimes "stabbing," and was felt in the lower part of the chest, more on the left side than the right. Operation for presumed gastric ulcer was undertaken at Woking Hospital in November, 1927. The patient, however, collapsed under the anæsthetic, and the abdomen was closed without investigating its contents. About the time of this operation he commenced to have some difficulty in swallowing; this persisted, and since the middle of June, 1928, he had become rapidly worse.

On admission to St. Thomas's Hospital no solid food could be swallowed, being returned at once unchanged. Some pain in the upper right chest was complained of. In appearance he was pale and thin, and looked ill. There was an area of dullness to percussion and absent breath sounds over the left base behind; the air entry over the whole of the left lung was diminished. The second aortic sound was much accentuated; the blood pressure was 135/85. There was a paramedian scar in the upper abdomen; no abnormal physical signs were discovered in the abdomen or in the nervous system. There was some pyrexia, ranging up to 101° F. Screen and film examinations with X rays showed a shadow passing out from the mediastinal shadow into the left lung area at the level of the bodies of the fourth to eighth dorsal vertebræ. No pulsation could be seen in the shadow. On swallowing opaque fluid it was seen that the œsophagus was displaced forwards and to the left, being stretched over the tumour and thereby partially obstructed.

The blood showed a leucocytosis of 17,200, polymorphs being 75 per cent. A Wassermann reaction was negative.

The Operation.

The diagnosis of aneurysm appeared very unlikely and exploration was decided upon, with a provisional diagnosis of mediastinal abscess, or possibly neoplasm. On August 1st, under intra-tracheal ether, the tumour was approached by a left posterior costo-transversectomy, removing the posterior two inches of the fifth, sixth, and seventh ribs, together with the corresponding vertebral transverse processes. The exposed parietal pleura was found to be pressed back by a firm hard mass in which no pulsation could be detected. Aspiration of this mass through the pleura withdrew no fluid. The posterior reflection of the pleura was gently separated from the sides of the vertebral bodies, where the exploring finger dropped into a large cavity. On withdrawing the finger there was a big gush of blood under considerable pressure, but hardly the pressure that would have been expected in an aneurysmal cavity communicating directly with the aorta. The colour, too, was a little less bright than that of the normal arterial blood. The hæmorrhage was arrested with gauze plugging, and the wound sutured without much blood having been lost.

The patient was nursed flat on his back, and kept well under morphia for the first 24 hours after operation. On August 3rd there was very little oozing from the wound, and the patient was comfortable and said that he could swallow better than before operation. On August 4th the wound was reopened under ether, it being hoped to replace the gauze plug with a muscle-graft sutured in position; but this proved impracticable as hæmorrhage became uncontrollable as soon as the gauze plug was disturbed. The tumour was again aspirated through the pleura; this time the syringe rapidly filled with blood, the piston being pushed forcibly back by the pressure. Hæmorrhage was again arrested by plugging and the wound partially closed. On August 6th he was able to swallow and his general condition was fair, but he complained of some pain. No blood was coming from the wound. On the 7th he twice vomited a little blood and became rapidly weaker; he died on the 8th.

Post-mortem Examination.

On reopening the operation wound little hæmorrhage was found. The floor of the cavity thus exposed showed a mass of laminated clot, bounded on the left by the pleura and on the right by the thoracic vertebræ, to which the clot was firmly adherent. No destruction of bone was found.

On exploring the body from the front a dissecting aneurysm was found, extending from the arch to the bifurcation of the aorta, and giving the appearance of a double aorta. The total length of the sac was 29 cm., its largest diameter was 5 cm., near its upper end, whence it tapered to 3 cm. at the diaphragm, and 1½ cm. at the lower end. The aorta was almost surrounded by the sac. In the middle of the thorax the sac had expanded into the cavity already described, limited by the vertebræ and pleura, and lined by laminated clot, some old, some recent. The thoracic part of the sac contained a considerable amount of old laminated clot and a small quantity of fluid blood, the abdominal part of the sac contained very little clot.

On slitting the aorta the intima was quite smooth and showed no evidence of disease. At the junction of the arch and descending aorta was a sharply raised ridge crossing the vessel transversely for a length of 1 cm. This ridge presented a sharp edge quite firm to the touch and suggested a fibrous scar. The lining of the sac, when stripped of its clot, showed a somewhat irregular yet smooth surface. 4 cm. below the diaphragm was a circular orifice 3 mm.

in diameter, with smooth rounded edges, connecting the aorta with the sac. The left bronchus was compressed and considerably narrowed by the sac; the lower lobe of the left lung showed deposits of fibrinous pleurisy, patches of broncho-pneumonia, and considerable areas of collapse. At the level of the crossing of the left bronchus there were two small perforations of the sac into the œsophagus, from which blood was oozing. The lower part of the œsophagus, the stomach, and the upper part of the small intestine contained several pints of fluid blood; death was due to this hæmorrhage. The heart was normal and no arterial disease was found elsewhere.

Microscopical Examination.—The ridge in the aortic arch showed a sharply defined fibrous scar extending through all the coats of the vessel; in the deeper part a collection of calcareous granules was present; beyond the scar tissue the aortic wall was normal. A section taken just above the bifurcation showed a healthy aortic wall stripped of its adventitia, which thickened and fibrous formed the wall of the sac. The sac was lined by a new intima.

It is suggested that the aneurysm started through a linear tear in the aortic wall at the junction of the arch and the descending aorta, which subsequently healed; and that communication between the aorta and the sac had been maintained through the round orifice below the diaphragm. The origin of this second opening is not clear, nor is any suggestion offered to account for the original cause of the lesion in the aorta.

We are indebted to Mr. Cyril Nitch for permission to operate upon and publish this case.

A CASE OF RUPTURE OF THE UTERUS.*

BY E. A. GERRARD, M.B. MANCH., M.R.C.S. ENG.,
RESIDENT OBSTETRIC SURGEON, ST. MARY'S HOSPITALS, MANCHESTER.

THE following case has some interesting features:—

The patient, a woman aged 34, who had had two children previously, was admitted to St. Mary's Hospital, Manchester, after the first of twins had been delivered by natural forces. The second twin was impacted, the hand and cord being prolapsed. Attempts at delivery by version had been made without success.

On admission the patient was in good condition with a pulse of 102. On abdominal examination the most obvious feature was the prominence of a fœtal limb to the left of the umbilicus. This was easily identified as a leg and the possibility of rupture of the uterus was discussed, but was ruled out owing to the excellence of the patient's general condition, the suggestion being made that the uterine wall was extremely thin from distension by twins and hydramnios. The pelvic measurements were normal. Vaginal examination revealed a prolapsed hand and foot and an umbilical cord which was not pulsating. There was no bleeding.

Under anæsthesia, delivery of the child was effected without difficulty by traction on the presenting foot. There being no abnormal amount of bleeding after this manœuvre, the patient was left to deliver the placenta herself. On palpation of the uterus abdominally a rather puzzling state of affairs was found. The impression gained was that the placenta had left it, but downward pressure failed to push it out from the vagina, and on drawing the uterus upwards the cord shortened. It was therefore presumed that the placenta was still in utero. After an hour's time there was no sign of the placenta, the patient's condition was not too good, but there was no cause for alarm. After two hours she was beginning to show signs of shock, and as there had been a little bleeding, a further anæsthetic was given to allow manual removal to be performed.

On introducing the hand into the uterus no placenta could be found, and one became aware of a large rupture of the anterior wall of the lower segment. The cord was therefore cut off short, the vagina carefully swabbed out with antiseptics and packed with sterile gauze, and the patient, who was by now in rather a critical state, was removed to the theatre.

On opening the abdomen the missing placenta was found in the region of the spleen. There appeared to be quite a negligible quantity of blood in the abdominal cavity, less than an ounce in fact, and there was no bleeding from the torn uterus which was well contracted, but it was deemed advisable to perform hysterectomy. This was done rapidly by the ordinary subtotal technique, except that an opening was left in the cervix for drainage. The pelvis was peritonised, the abdomen mopped out, and the abdominal wall sutured in layers, without drainage.

Intravenous saline was given and the patient treated for shock on the usual lines, but she was placed in Fowler's position as soon as it was deemed advisable. She had a swinging temperature and some vaginal discharge for a week following operation, but the abdominal wound showed no signs of suppuration, and she was able to proceed home within three weeks.

The points of interest in this case seem to be: (1) The small amount of hæmorrhage, due presumably to the situation of the tear, and in contrast, the present writer saw a case about a month later where a woman was admitted to hospital with a breech born as far as the head which was hydrocephalic. While the instruments were being boiled the patient suddenly cried out, collapsed, and was dead within ten minutes. Post-mortem examination revealed a tear through the uterine artery. (2) The fact that one of the child's legs was probably projecting through the rupture into the abdominal cavity when the patient was admitted and would have given the diagnosis had her condition not been so good. (3) That the placenta and membranes should be delivered into the cavity of the abdomen. (4) The delayed onset of shock which did not appear until six hours after the rupture had taken place. This case is reported by courtesy of Dr. J. W. Bride.

* Communicated to the North of England Gynæcological and Obstetrical Society on Oct. 26th, 1928.

A CASE OF FAMILIAL HÆMOLYTIC ICTERO-ANÆMIA.

BY C. G. L. VAN DIJK, M.B. EDIN.,
HON. SURGEON, PRETORIA HOSPITAL;
AND
ADRIANUS PIJPER, M.D. LEIDEN,
PATHOLOGIST TO THE PRETORIA HOSPITAL.

THIS case is recorded because, as far as we know, it is the first properly observed case of this nature amongst the older white population of South Africa, and also because we want to make it more widely known that the diffraction method of measuring red cells provides an easy and reliable means not only of establishing a diagnosis, but also of tracing the hereditary character of the disease to its origin.

The patient was a girl, 23 years of age, looking well nourished and not obviously ill, apart from a definite icterus. As far back as she could remember her complexion had always been sallow. She had always been easily tired, and had never felt well. When still quite a child she had experienced attacks of pain in the upper part of the abdomen. Since then she had had several attacks of severe pain in the region of the gall-bladder. Various medical men were consulted from time to time, and she was treated for malaria, pernicious anæmia, and cholecystitis.

On the first occasion that she consulted us she had been to a dance, and on her arrival at home had been seized with acute pain over the gall-bladder. The attack was typical of gall-stone colic. During the next few days she had several attacks, and we found great tenderness over the gall-bladder, which could not be felt. The liver was not obviously enlarged, but the spleen was greatly enlarged, extending to the right almost to the middle line and downwards almost to the left iliac crest. The surface was smooth. There was nothing in the family history to suggest familial hæmolytic jaundice. Examination of a blood-smear, in order to settle the question of Addisonian (pernicious) anæmia by means of the diffraction micrometer, revealed a marked microcytosis. With the present instrument the diameter of the red cells in normal persons is found to be 7·3 microns, with individual variations, which, however, do not exceed 0·4 micron. The patient's red cells measured 6·4 microns. This at once established the diagnosis of hæmolytic jaundice, and a complete blood examination showed: hæmoglobin, 52 per cent.; red cells, 3,500,000; reticulocytes, 14·5 per cent.; hæmolysis, beginning at 0·7 per cent. and complete at 0·4 per cent.; van den Bergh's test direct negative, indirect positive; polymorphonuclear leucocytes, 72 per cent.; small lymphocytes, 22 per cent.; large mononuclear leucocytes, 5 per cent.; eosinophils, 1 per cent.; Wassermann reaction negative. This constituted a perfectly typical picture.

Splenectomy was performed a few days later. The abdomen was opened under local anæsthesia, and the patient was then put under light general anæsthesia. The incision was made half an inch to the left of the mid-line. A few adhesions on the posterior surface of the spleen were freed. The pedicle presented no great difficulty, and the spleen was removed in the usual way. Three accessory spleens were found and were also removed. The gall-bladder was found to contain a large number of stones. Cholecystotomy was performed, and the stones (30 to 40 in number) removed. The gall-bladder was closed without drainage. The stones ranged in size from that of a small pea to a pigeon's egg, one of the larger stones being found in the common duct. Cholecystectomy was decided against, as the patient's condition on the table at this stage was not satisfactory. The abdomen was closed without a drain, and the wound healed by first intention.

The spleen weighed 881 g., the accessory spleens together weighed 5 g. They were all dark purple and extremely congested, the cut surface was deep red, and the Malpighian corpuscles sparse and indistinct. The accessory spleens showed all the changes present in the large spleen, but to a lesser degree. The trabeculæ were not conspicuous, and the arteries often showed thickened dense white walls. Microscopically the pulp was filled with blood, and the lymph follicles were spare and often without germ-centres. The reticulum was scanty, and the sinuses relatively empty and collapsed and lined with the peculiar endothelial cells described by Meulengracht, containing large, round, prominent nuclei and standing packed side by side. Pigment was distributed throughout all the elements of the spleen. That part of it which gives an iron reaction was found in sinuses, in pulp-cells, and in the intima of many arteries. In the sinuses it showed a honeycomb appearance, as if the spaces between a number of blood-cells had been stained and the cells themselves had disappeared. In the pulp the pigment was diffused through the whole protoplasm. The largest amount of iron pigment was in the arterial walls, and it was present in many elastic tissue strands.

A week after the splenectomy the hæmoglobin had risen to 85 per cent. and the red cells to 4,500,000, but there were still 14 per cent. reticulocytes; van den Bergh's test was still indirectly positive, and the diameter of the red cells had increased to 6·6 microns. Sixteen days after the operation the hæmoglobin reached 98 per cent., the red cells remaining at 4,500,000, whilst the reticulocytes had come down to 7 per cent. The van den Bergh's test was then negative, and the red cells showed a further increase in diameter, measuring 6·7 microns. A final examination was made one month after the operation. The hæmoglobin was then 100 per cent., the red cells 5,360,000, with 9 per cent. reticulocytes, van den Bergh's test giving a faint indirect positive. Hæmolysis started at 0·46 per cent. saline, and was complete at 0·3 per cent. saline. The red cells again measured 6·7 microns. Clinically the patient was perfectly well and very pleased with what had been done. It is, of course, well known that splenectomy in these cases has a marked beneficial and lasting effect, but that it does not altogether abolish the objective signs of the disease.

The familial nature of the disease in this case could be investigated through the active coöperation of the family physician, Dr. I. Rosenberg, who kindly prepared blood smears of the nearest relatives. Upon measuring their blood-cells by means of the diffraction micrometer it was found that the mother of the patient showed the quite normal diameter of 7·3 microns. The father's cells, however, measured 6·6 microns, one brother's 6·8 microns, another brother's 6·7 microns, a sister's 6·8 microns, and a paternal uncle's 6·9 microns. An inquiry into the medical history of the relatives on both sides, undertaken by Dr. Rosenberg, was quite negative, except in the case of the father. His history mentioned an attack of "inflammation of the liver," and later an attack of jaundice, supposed to have been "catarrhal."

Without going into the controversy about the relationship between microcytosis and the pathology of the disease called familial hæmolytic icterus, it seems quite obvious to us that our case contained a hereditary element, and that this was inherited through the father, and was present in the father's blood relations and absent in the mother, and that the presence of this hereditary character expresses itself in the average diameter of the red blood-cells, as measured by the diffraction micrometer.

Medical Societies.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

AN EXPERIMENTAL STUDY OF YELLOW FEVER.

Prof. EDWARD HINDLE, Sc.D., the Beit Fellow in Tropical Medicine, gave a lecture to this Society on Jan. 17th, describing his recent work on yellow fever in monkeys, with special reference to the method of vaccination discovered by him, and to other aspects of prophylaxis.

He began with a brief account of the present distribution of yellow fever, drawing attention to the fact that West Africa is now the main endemic centre of the disease. After referring to the discovery by Stokes, Bauer, and Hudson that Asiatic monkeys, and especially *Macacus rhesus*, could easily be infected, he described the way in which he succeeded in getting the virus of the disease brought back to London by Dr. Andrew Sellards. With the liver of an infected monkey that had been kept frozen during the voyage from Senegal to London, a period of 12 days, the disease was reproduced in this country, in a rhesus monkey, at the end of March, 1928. Since that date the strain had been maintained at the Wellcome Bureau of Scientific Research and had been the subject of the experiments and observations to be described. This strain of yellow fever had been isolated from a Syrian at Dakar, who suffered from a very mild attack, yet in monkeys the disease had shown a very high degree of virulence, the animals almost invariably succumbing to the infection. As a general rule transmission from one monkey to another was effected by the subcutaneous inoculation of a small quantity of infected liver, ground up in normal saline. In a series of 50 monkeys inoculated with fresh virus there was not a single recovery, except when sublethal doses were employed. The liver, spleen, and kidney of monkeys dying of the disease were found to contain variable amounts of virus, ranging from 1000 to 100,000 minimum lethal doses per gramme. The inoculation of 0·0001 g. of infected tissue was usually as effective as 1–2 g. in producing the disease, but when doses of 0·00001 g. were employed the incubation period was lengthened. In two instances the inoculation of this dose caused no rise in temperature nor any other signs of infection, yet the animals were found to have been immunised, and subsequent inoculations of very large quantities of virus had no effect.

In monkeys an incubation period, usually of three days, was followed by a rise in temperature of about 2° F., which lasted for 36 to 48 hours, succeeded by a sudden drop to subnormal, and the death of the animal about five days after being inoculated. The symptoms in monkeys dead of the disease, with the exception of minor differences, resembled those in human patients.

It was found that the frozen virus preserved its virulence for about 18 days, after which period it acted as a vaccine. Thus animals inoculated with the liver of infected monkeys, kept frozen for one to three months, showed no sign of infection but were immune against subsequent inoculations of fresh virus. Similarly, it was found that the virus could be dried in vacuo, and, if kept absolutely dry, preserved its virulence for at least four months, and probably longer. If, however, this dried virus was exposed to moist air, it gradually lost its virulence and could then act as a vaccine.

Mosquito Transmission.

Prof. Hindle described his technique of handling infected mosquitoes and then gave the results of his transmission experiments in this country with both

an African and Indian race of *Aëdes aegypti* (*Stegomyia fasciata*). The disease, he said, was readily transmitted to monkeys by the bites of mosquitoes that had fed on an infected monkey at least nine days previously. Both races of mosquitoes could carry the infection, but there was a suggestion that the Indian race was a little less susceptible than the African one. In addition, experiments were described showing that insects might harbour the virus without producing infection by their bite. This was the first proof that the Indian race of *Aëdes* is capable of transmitting yellow fever, and now there could not be any doubt that if by any ill chance the disease ever reached the Orient, the local race of mosquitoes could serve as an efficient carrier. The stringent quarantine regulations concerning this disease were fully justified by the results of these experiments.

Immunity.

It had been known from early times in the history of the disease, Prof. Hindle continued, that an attack was followed by a high degree of immunity, and the serum of convalescent patients, if inoculated into monkeys, would protect them against infection for about one month. The presence of active immune bodies in the blood of recovered patients furnished a means of finding out whether a person had had the disease, for it was only necessary to inoculate a rhesus monkey with the serum of a suspected convalescent case and at the same time with yellow fever virus. By this means in West Africa the Rockefeller Commission had detected the existence of yellow fever in villages where no obvious signs of the disease were present.

Employing these methods the nature of two atypical cases of yellow fever contracted in the laboratory had been discovered. In both patients (the lecturer and his laboratory attendant) the symptoms, a sharp fever of short duration, had closely simulated and at the time were attributed to influenza. After the fever, however, in both cases the blood contained immune bodies against yellow fever, as tested by inoculation into monkeys, and therefore there could be no doubt about the nature of the attacks. It might be added that jaundice and albuminuria, although looked for, were not detected, and the only characteristic symptom was hyperæsthesia of various parts of the body in one patient, which persisted for three to four weeks. These results, combined with the production of immunity by the inoculation of sub-lethal doses of virus, furnished additional evidence in support of the view that mild cases of yellow fever might occur which presented none of the ordinary symptoms of the disease. These cases would never be recognised in the ordinary course of events, but would be capable of infecting mosquitoes that fed on them and thus maintaining the infection in a latent or hidden form.

It was an interesting example of tissue immunity, said Prof. Hindle, that the liver and spleen of monkeys that had recovered from yellow fever, when inoculated into normal monkeys in 1·0 g. doses, was found to immunise them against subsequent inoculations of fresh virus. The brain, kidney, and lymphatic glands of convalescent monkeys did not possess this property.

The inoculation of hyperimmune serum into infected monkeys, after the commencement of fever, was found to have no obvious effect on the course of the infection and consequently doubt was expressed as to the value of serum treatment in human cases of yellow fever. Hyperimmunised monkeys, when inoculated with large doses of infected liver, were found to succumb within 48 hours to a peculiar type of anaphylaxis. Ordinary immunised monkeys were unaffected by the inoculation of similar doses.

Vaccination.

Great hopes had been placed on Noguchi's vaccine prepared from *Leptospira icteroides*, supposed by him to be the causative organism of yellow fever. It was now known that this organism was identical with that of Weil's disease (spirochætosis icterohæmorrhagica), therefore the vaccine prepared from it could hav no value in yellow fever prophylaxis and its use ha now been abandoned. The re-establishment of th earlier view that this disease is caused by a filterabl virus had led Prof. Hindle to apply the methods o vaccination which had proved successful in th production of vaccines against such diseases as fow plague and dog distemper. In June, 1928, he showed that a phenol glycerine emulsion of the liver and splee of infected monkeys conferred a high degree o protection against very large amounts (10,000 t 100,000 lethal doses) of the virus. A formalinise suspension had the same vaccinating property During the past six months these experiments hav been extended, the earlier phenol glycerine vaccin being replaced by a formalinised one, as the injectio of glycerine was painful. The present method o preparing the vaccine was as follows :—

The liver and spleen are removed from an infected monke killed in the last stage of the disease, when the temperatur has become subnormal. These organs are weighed an ground up in a mortar with fine sand. A measured quantit of 9 per cent. salt solution, equal to half the original weigh of these tissues, is added and the mixture allowed to stan for a few hours. Then distilled water is added, equal t nine times the volume of the strong salt solution. As result all the cells are cytolised, liberating the containe virus, and a 20 per cent. suspension of tissue extract i normal saline is obtained. This suspension is allowed t sediment, then filtered through muslin. Part of it is teste for virus content, and a 1 in 10,000 dilution of the origin tissues should produce a fatal infection in a monkey.

The virus suspension is killed by the addition of 2 per 100 formaldehyde and after 24 hours can be used as a vaccine if it passes the usual sterility tests.

Aragão adds 0·5 per cent. phenol to this suspension, i addition to the formaldehyde. Both phenol glycerine an formalinised vaccines, when kept in the ice-chest, have bee found to preserve their properties for some months. Th first has also been dried in vacuo and found to retain it properties.

Monkeys inoculated with these vaccines develope a high degree of protection against yellow fever, an this protection had been tested against the inoculatio of fresh virus and the bites of infected mosquitoe up to four and a half months after vaccination without showing any signs of diminution. In mos cases, about ten days after being vaccinated, th monkeys were inoculated with 0·1 g. infected live material, equivalent to 1000 to 10,000 lethal doses and in some instances with very much greater quan tities of virus. The results of the first series o experiments which were given in detail suggeste that when the amount of virus in the infected monke falls below 10,000 minimum lethal doses per gramme any vaccine made from its tissues gives only partia protection. With tested vaccines a very high degre of protection was obtained, and this in spite of th fact that enormous doses of virus were used to tes the vaccinated animals, *equivalent to at least 100 times the dose which invariably produced fatal infection in normal animals.* In addition the severity of th tests was enhanced by the short interval betwee vaccination and inoculation which was hardly suffi cient to allow the full development of protection.

The lecturer's results had been confirmed, he said by A. Pettit and his collaborators working in Paris and by H. de B. Aragão in Rio de Janeiro, wh used a Brazilian strain of yellow fever. Aragã obtained constant protection in monkeys, and there fore tested the vaccine in human beings, using 20 per cent. suspension of liver, spleen, brain, an kidney containing 2 per 1000 formaldehyde and 0·5 pe cent. phenol. This vaccine was administered sub cutaneously in 2 c.cm. doses to the laboratory worker at the Institute Oswaldo Cruz, with no ill-effects and subsequently used in a small epidemic of yellow fever. Between 300 and 400 people were vaccinated including the health officers working in the infecte neighbourhoods, and people living either in th same house or in the vicinity of yellow fever cases

[1] Brit. Med. Jour., 1928, i., 976.

although no unwarranted conclusions had been drawn it was noted that none of the vaccinated contracted the disease, although some of them must have been exposed to infection. These results were considered so favourable, that the vaccine was now being prepared on a larger scale for use by the Public Health Department of Brazil.

With regard to the position in West Africa it was pointed out that there is an urgent necessity for some additional method of protection against yellow fever, as evidenced by the number of past epidemics, and at present there seemed to be no likelihood of anti-mosquito campaigns succeeding in eradicating all chance of infection. Accordingly, the Colonial Office had decided to give Prof. Hindle's yellow fever vaccine a trial in the West African Colonies, and had invited the Wellcome Physiological Research Laboratories to undertake its production on a large scale.

In conclusion, the lecturer expressed his opinion that by the general use of this vaccine, of proved efficiency in monkeys, there was every hope of yellow fever ceasing to be a source of danger in the world.

Sir JAMES KINGSTON FOWLER, in proposing a vote of thanks to Prof. Hindle, called attention to the work of the West African Yellow Fever Commission of the Colonial Office (1913–15), and pointed out that many of the views expressed in their reports had proved a foundation for subsequent work on the disease.

ROYAL SOCIETY OF MEDICINE.

SECTIONS OF PATHOLOGY, SURGERY, AND GYNÆCOLOGY.

A COMBINED meeting of these Sections was held on Jan. 18th with Dr. J. S. FAIRBAIRN, President of the Section of Gynæcology, in the chair, to discuss

POST-OPERATIVE THROMBOSIS.

Dr. W. HOWEL EVANS, in opening the discussion, said the problem of thrombosis was many sided, and a question which had always interested the clinician and the pathologist, in trying to account for post-operative thrombosis, was whether there was any evidence of alterations in the blood which might promote coagulation, and if so, what their importance was in relation to other factors. There was now evidence that some of the factors concerned in coagulation might be disturbed. Dr. Howel Evans wished to extend the consideration to thrombosis occurring after parturition, after fractures, and after acute fevers, such as pneumonia. All these forms presented points of similarity. All were associated with tissue injury and the subsequent absorption of breakdown products; in all there was imposed on the patient a period of enforced restraint or immobility; in all the thrombosis, with or without embolism, occurred some days after the original trauma. And running through all was an increase of the blood-platelets, whilst in some at least there was evidence of an increase of fibrinogen in the blood.

It had long been known that tissue juices contained a thromboplastic material or thrombokinase, which was able to produce coagulation. This it could do by the activation of a mother-substance, prothrombin, in the presence of calcium-ions, in this way forming thrombin, which clotted fibrinogen. Also something in the injured tissue had the power to provoke an increase in platelets and fibrinogen, though the nature and mechanism of those substances seemed at present obscure. It was now clear, too, that conversion of fibrinogen to fibrin was a central feature of the process of coagulation. Blood fibrinogen was also increased during pregnancy. The blood-platelet was a definite kind of cell, arising in the bone-marrow, which was destroyed by the reticulo-endothelial system. By their disintegration these platelets provided material which was intimately associated with the formation of thrombin and the coagulation of fibrinogen. If when blood was shed these platelets were prevented from disintegrating or were filtered off, the blood showed no tendency to spontaneous coagulation. In static thrombi the first step in the building of the thrombus was the adhesion of platelets to the vessel wall, followed later by the formation of fibrin. This adhesion to the wall might be helped by a slowing of the circulation. There was a parallelism between the number of circulating platelets and the tendency to coagulation in the various diseases.

The speaker, with his colleagues, had studied 50 cases following operation, these ranging from minor to large abdominal operations. Before the operation, in most, the platelet count was about the normal, but four to six days after operation it rose, reaching its maximum at about the tenth day, and normal was reached in another ten days. In many cases having a major operation the increase was 100 per cent. to 150 per cent. The age of the patient did not affect the increase, neither did exercise, massage, or movement following the operation. A study of 28 cases following parturition gave a similar result, and the results were most striking following Cæsarean section, as after this operation the platelets rose more quickly, and gave an average increase of 200 per cent., the maximum being reached in ten days. The return to normal was slower than after the other operations. In 11 cases of simple fracture, mostly of the lower limbs, with confinement to bed, a similar curve was seen. A similar observation was made in the case of fevers. From control observations it was evident that the platelet reaction occurred independently of simple loss of blood, anæsthesia, and rest in bed. In sepsis the platelets varied irregularly. The evidence supported the use of post-operative exercises, and Dr. Howel Evans suggested that search might be made for some anti-coagulent substance or drug which would hinder the lysis or reduce the agglutinability of the platelets.

Mr. D. H. PATEY said that four manifestations of post-operative thrombosis were met with—namely, localised thrombosis, massive pulmonary embolism, minor pulmonary embolism, and latent thrombosis. The first two of these were most easily studied and most readily diagnosed. He did not think the tissue juice absorption theory of causation could be supported on the evidence. Neither did he consider that the sitting-up position of the patient after operation was a factor in localising the thrombotic process. One surgeon who, after operation, kept all his patients flat on the back experienced no less a tendency for them to develop thrombosis and embolism. Mr. Patey considered that Dr. Howel Evans's work on the blood-platelets marked a definite advance in knowledge on this subject. But in order to put this theory on a firm basis it would be necessary to furnish unequivocal proof that after splenectomy—the operation after which the rise in the platelets was most marked—there was special liability to thrombosis and embolism. It was a phase of the subject which might well be looked into. Mr. Patey thought that the stasis aspect of the subject—the only one which could in any degree be controlled—offered the most hopeful side for attack. Not only was the inhibition of the diaphragm an important matter, but the question of the effect of the incision on the muscular abdominal wall was equally so. Skiagrams which the speaker exhibited showed distinct inhibition of the diaphragm due to pain, and he said there was no way of getting over that inhibition due to pain, though deep-breathing exercises did much to induce movement in a sluggish diaphragm. Any good effect produced by morphia was spoilt by the lack of tone it caused in muscle. He thought too much attention had been concentrated on the diaphragm in these cases and too little on the abdominal muscle. The effect of the operation on the abdominal wall was two-fold; its tone was diminished, so that it gave a less effective response, and its response was irregular. Much could be done by proper abdominal massage to send the abdominal wall to the diaphragm. In conclusion, Mr. Patey said he felt the

profession was now definitely advancing towards the elucidation of this problem, and that Dr. Howel Evans's work on the blood-platelets was a very pronounced contribution; the actual solution, he felt, would come from the laboratory. Important additions to knowledge on it would, however, arise from old and well-thought-out clinical methods and experiments accurately recorded.

Mr. VICTOR BONNEY first commented on the discordance between clinical facts at the present time and the consequent confusion in which the subject was shrouded. The process might be either bacterial, toxæmic, or hæmic, the latter implying some alteration in the blood itself. In favour of the bacterial idea was the fact that a thrombosis which was obvious, either by the clot being palpable or by visible signs of venous blockage, was always preceded by fever and local pain and other signs of inflammation. On the other hand, cases of pulmonary embolism did not usually exhibit these symptoms before embolism, though there was pain and fever afterwards. Thrombosis, if bacterial, bore no relation to the degree of septicity in the operation area, being, indeed, commoner after so-called "clean" operations than after those in which there was much suppuration. Thrombosis after labour was not usually accompanied by symptoms of typical puerperal fever, but occurred independently in the second or third week, as though it were an entity in itself. The toxic idea Mr. Bonney thought unlikely. Post-operative thrombosis was almost entirely limited to the veins of the lower half of the body, chiefly the legs, and of the legs usually the left one. Toxæmic lesions were generalised, not picking out any region. With regard to the hæmic view, Mr. Bonney pointed out that in hæmophilia lesions were generalised. Thrombosis was rare after operations on the uterus via the vagina, and this seemed to suggest that trauma to the uterus did not suffice to cause thrombosis unless trauma was also caused to the peritoneum. The occurrence of thrombosis after parturition was, however, against this. The symptoms appeared at a significant period—i.e., from the tenth day onwards—whilst in ordinary infection the symptoms appeared in two or three days. Therefore the causal organism in thrombosis did not belong to the group of ordinary septic organisms, the incubation period of which was short. Possibly, he suggested, post-operative thrombosis was due to anaerobic spore infection from the patient's own bowel. Catgut blisters he thought were due to the growth of certain anaerobic sporing organisms in the catgut, and if that were so, they were derived from the animals from which the gut was taken. *Bacillus coli* appeared in the urine after all abdominal sections. Mr. Bonney felt that the research of Dr. Howel Evans was very hopeful.

Discussion.

Mr. J. P. LOCKHART-MUMMERY considered that the problem of post-operative thrombosis was almost entirely a physiological one, and it was not likely to be solved until much more was known about intravascular clotting, a subject as yet only partially understood. This thrombosis admittedly occurred far oftener after abdominal operations than after any others, and he thought it was rightly assumed to be due to interference with movements of the abdominal wall. Even after labour there was a badly stretched abdominal wall which did not afterwards contract properly. It was also agreed that the common time for the occurrence of post-operative infarct was about the tenth day. He believed that the thrombosis in the vein occurred at, or immediately after, the operation, and that the reason of the symptoms at the tenth day was the softening and movement of the clot. Sepsis as a cause need not be seriously discussed. A hundred years ago John Hunter had found that if the jugular vein of a normal horse were tied in two places intravascular clotting did not take place. If at the end of a fortnight that vein were opened which had been tied off, the blood was still fluid, so that mere stasis did not cause clotting. If blood were withdrawn from a vein without the needle having touched its wall in any way save at the point of puncture, the blood so withdrawn could be kept in the laboratory for three weeks without clotting, though in that time it might decompose. If, however, even the slightest trace of thrombokinase were added to the withdrawn blood it immediately clotted. There was no means of preventing thrombokinase getting to the blood when patients were cut, but to some extent stasis in the veins could be prevented. A tight packing of the abdomen after the operation would tend to hold it so steady that the diaphragm would have a better chance of action without causing great pain.

Prof. TOM HARE (who had worked in association with Prof. E. E. Glynn) gave some results of an inquiry into the ætiology of lamb dysentery, which bore some resemblance to melæna neonatorum in human babies. The blood of 11 healthy ewes was examined and the initial counts were made within 5 to 15 days before parturition, the latter process having been, in all, natural and unassisted. One post-partum count was made in each case. He exhibited a table showing that the findings as to the rise in the platelets after parturition agreed with those of Dr. Howel Evans.

Dr. F. J. MCCANN said that much could be done clinically to prevent post-operative thrombosis. In the vast majority of cases he thought the cause of the condition was the surgeon at the operation, either in that he was guilty of errors of technique during the operation or in mistakes made in after-treatment. Efforts should be made to diminish the pain in the abdominal wall. A stitch tied very tightly caused agony until it had cut its way out, and such intense pain had a great influence on the diaphragmatic contraction. If the stitching of the abdominal wall was done without constriction, the surfaces being no more than opposed, little pain after operation would ensue, and Nature's glue would do the rest. Thick material should not be used for sutures. And in the after-treatment a very important matter was movement from the first and allowing patients to lie in any posture they found comfortable. The knee-pillow should be abandoned; it was an important disposer to stasis in the femoral vein. Dr. McCann had not had a case of pulmonary embolism in his 25 years of practice.

Mr. D. LEVI said that in the blood there were thrombin substances which made the blood clot, also heparin which stopped clotting, the latter having been discovered in America. This was very potent, 0·1 g. sufficing to stop coagulation in 40 c.cm. of blood, while 0·1 g. per kg. of animal weight stopped coagulation in an intact animal. It could be sterilised by boiling, and was capable of being injected intravascularly without producing untoward effects.

Mr. CECIL ROWNTREE said all practical surgeons would congratulate Dr. McCann on the success which had attended his surgical endeavours, though the procedures he carried out were used by others whose work was not free from these accidents. It seemed to him there was a danger in this discussion of trying to make the facts fit in with the preconceived hypotheses. The thrombosis under discussion did not always follow operations. He had hoped Mr. Bonney would have given the percentage incidence of the complication after normal labour, when it did sometimes occur. Sometimes a patient died from the accident on the third day. If a patient of his got an obvious femoral thrombosis he, the speaker, felt happy, because he knew that patient would not get a pulmonary embolus. He did not think embolism had any relation to sepsis as ordinarily understood. A friend suggested to him 18 months ago that the administration of large doses of alkali after an operation might so alter the hydrogen-ion concentration as to increase the clotting time, and so avoid thrombosis. It was yet too soon to pronounce on that.

Dr. W. CRAMER pointed out that in the discussion no distinction was made between intravascular

clotting and thrombosis. In both the ultimate result was the same, but intravascular clotting produced by the injection of tissue extracts was a process which took place in a few seconds, whereas thrombosis as clinically seen was a slow process, whose beginning took place, as Mr. Lockhart-Mummery pointed out, at the time of operation. The microscopical structure of a clinical thrombus supported that view. He considered that a thrombus began as a mass of agglutinated platelets with practically no fibrin. Fibrin was formed when the blood-platelets disintegrated, which was different from agglutination.

Miss FRANCES IVENS expressed the hope that Dr. Howel Evans would continue his researches and include in them an investigation of the toxæmias of pregnancy. In her experience thrombosis was much more apt to occur when these toxæmias were present. Possibly substances let loose in the circulation at operation had much to do with the causation of thrombosis.

Dr. HOWEL EVANS, in a brief reply, agreed that post-operative thrombosis was a physiological result. He did not wish to give the impression that he believed that what had been found out concerning the blood-platelets explained the whole matter; but it showed a peculiar physiological response to trauma. A necessary prelude seemed to be tissue destruction and absorption of such products. There might be subtle qualitative changes in the corpuscular constituents or the plasma of which nothing was yet known. Another point was that after splenectomy for splenic anæmia mesenteric thrombosis not infrequently happened. Rosenthal had published a series of cases bearing this out.

Mr. VICTOR BONNEY also replied. He said that formerly he strapped patients rigidly after operation, but most of them would not endure it, consequently he had abandoned the practice. He agreed that it was a means of stopping post-operative distension. In answer to Mr. Rowntree's remark about normal labour, Mr. Bonney agreed that it was another disquieting fact which complicated the study of this accident. He joined with others in assessing highly the value of Dr. Howel Evans's researches, and added that he thought there must be something local which determined the onset of the thrombosis.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AT a meeting of this Society held on Jan. 18th, with Dr. J. HOWARD-JONES, the President, in the chair, a discussion on the

INSPECTION AND REGISTRATION OF NURSING HOMES

was opened by Dr. J. J. BUCHAN, who confined his remarks to the administrative and legal aspects of the Nursing Homes Registration Act which came into force on July 1st, 1928. Considerable abuses from the hygienic, medical, and social points of view had been known, he said, to medical officers of health for some time before the Act. Complaints had reached them by circuitous routes and their society had been duly impressed, more so than had the British Medical Association and Ministry of Health. It was, in fact, the representations of the Society of Medical Officers of Health and of the College of Nursing that had led to the passing of the Act. The legislation was a first attempt, but it was so imperfect that it would require almost immediate modification to put it on a sound and practical basis. In the first place a nursing home was defined in very general terms as "any premises used or intended to be used for the reception of and the providing of nursing for persons suffering from any sickness, injury or infirmity." It excluded asylums and institutions under the Lunacy Act of 1890 and the Mental Deficiency Act of 1913, and any place under the control of government or incorporated by Royal Charter, but included all surgical, medical, and maternity homes. The definition, however, went much further than that and brought in convalescent homes, and places for the reception of aged and infirm persons. The Act tried to deal with all these varied institutions as if they were one. Section 1 (3) said that "the local supervising authority shall, on the receipt of an application for registration, register the applicant in respect of the nursing home named in the application and issue to him a certificate of registration." Thus the duty was laid on county councils and county borough councils of registering the home provided it was suitable for the purpose named in the application. There was nothing to prevent a keeper applying for registration as one kind of home, securing a certificate as suitable for that purpose, and then using his premises for another kind of home. The only appeal would be to the court of summary jurisdiction at quarter sessions, and that court would look on the legal position and not on the medical aspect of the case. Dr. Buchan had been advised that it was quite possible within the terms of the Act to use a convalescent home—registered as a "nursing home"—for maternity, and to be a "registered maternity home" without committing a punishable offence. The local authority in such a case would have no authority to cancel the registration. This was a point of real difficulty and one in which the difficulties would increase with time, and it might well do away with the good expected to result from the Maternity Homes Act of 1926. The great objection to the new Act was this way of dealing simply with a very complicated subject. If an old bedridden woman paid a neighbour 15*s*. a week to look after her, the cottage would almost become a "nursing home" under this Act. Any simple procedure such as that set forth in the Act was practically impossible; power should have been given to local authorities to differentiate between the different classes of nursing homes. To demand the presence of registered nurses for aged persons in cottages was an absurdity. The Act was peculiarly unworkable. Dr. Buchan's practice was to ask the medical officer for maternity and child welfare to carry out the inspection under the Act through her health visitors, and to ask the chief sanitary inspector to detail an inspector to look into the sanitary accommodation.

Dr. A. MIDDLETON HEWAT agreed with Dr. Buchan that there were great difficulties in working the Act, and that its wide terms led to differences in interpretation. The first difficulty that arose was presented by the word "nursing" in the definition. It was necessary to prove that nursing was provided in homes for the aged and infirm if these were to be registered, and it was not always easy to know where nursing began and ended. Abuses were often found in these places, and it was as well to include as many as possible under registration. A second difficulty was produced by the definition of a maternity home as "any premises used or intended to be used for the reception of pregnant women or of women immediately after childbirth." In London there were many homes for pregnant unmarried girls who were taken in early in pregnancy and sent elsewhere for their confinements. Under this definition these places became "nursing homes."

Grounds on which Application for Registration may be Refused.

Section 1 (3) enumerated the grounds on which a local authority might refuse to register an applicant: (*a*) "that he is not a fit person whether by reason of age or otherwise." In London it had been ruled that 21 was the minimum age, but no maximum had been fixed, and some homes had been registered where the keeper was getting on in years and it was doubtful whether he or she was fit for the work. Elderly trained nurses, too old for other work, often took in aged and chronic patients, and these institutions needed watching. (*b*) "For reasons connected with situation, construction, accommodation, staffing

or equipiment," the registration might be refused. The existence of an offensive trade next door or of some special fire danger, such as a garage below, would constitute reasons connected with situation. It was the London practice to fix definitely the number and type of cases that might be accommodated in each room, not in the whole building. The space was measured and plans were drawn up by the architect. The certificate stated precisely how many cases might be admitted to each room—e.g., two surgical or medical, or one medical case only. 960 cub. ft. were allowed for mother and baby, 800 cub. ft. for a mother only, 700 cub. ft. for a surgical, medical, senile or chronic case, and 600 cub. ft. for an ante-natal case. In a few cases where the cubic capacity had fallen slightly below the standard, registration had been allowed on a satisfactory square measurement. That it was legally possible to specify the type of case was shown by the same subsection, which went on to say, "fit to be used for a nursing home of such a description as the nursing home named in the application." The classification of cases adopted was: maternity, surgical, medical, and chronic or senile. Of course, many rooms were registered for all or several types of case. There was no objection to nursing surgical cases in a maternity ward, and one bed might be used alternatively for either kind of patient, provided suitable precautions were taken if a septic case occurred. It was, however, the rule that, if a room with more than one bed were used for a maternity case, the other beds should only be used by maternity cases. Women did not like to have their babies in a mixed ward. Mental and alcoholic patients were not allowed in the same home as maternity cases. Many untrained and incompletely trained women were posing as nurses without the knowledge of their patients, and the Act had been initiated to meet this abuse more than any other. Hard-and-fast rules could not be laid down; the number of trained nurses must depend on the number and relative proportion of the cases. In an ordinary nursing home the London County Council required two day and one night nurse for every six patients and one nurse on night duty for every four patients, or for any one patient who was acutely ill. If the keeper were a midwife in practice, she had to make some arrangements for the care of her patients while she was out.

Subsection (3) (*c*, *d*) insisted that the keeper of the home should be a qualified nurse, and to this London had strictly adhered, with the one exception of the small home for senile chronic cases. These were registered if the keeper was a good type of woman and reliable, even though untrained. There was no regulation as to the proportion of qualified to unqualified on the staff, but the inspectors tried to persuade keepers to employ as many qualified nurses as possible. Particular notice was taken of the accommodation provided for the staff, both bedrooms and sitting-rooms. The equipment demanded must depend on the type of home. For the guidance of keepers a leaflet had been printed setting out a standard minimum; the floors must be covered with linoleum or polished; venetian blinds were not allowed; washable covers must be provided for upholstered furniture; each bed must have so many sheets, towels, and blankets; there must be a locked poison cupboard, and a sufficiency of such things as cans, bowls, dressings, and so on. A very important point was fire precautions. No nursing home should be registered without the coöperation of the borough surveyor. Every home in London was inspected by a member of the fire brigade and an architect. Special provision was made in Section 1 (3) (*e*) for new maternity homes; registration was to be refused if "any person employed in attending any woman in the home in childbirth or in nursing any patient in the home is not either a duly qualified medical practitioner, a certified midwife, a pupil midwife, or a qualified nurse." If, now, an old surgical home wanted to register for five maternity beds, it would become a new maternity home under this section. The provisions of the section could not be made to apply to the whole home, so a note was usually put on the certificate that no maternity case should be attended by any but the class of persons listed.

London had adopted practically unchanged the model by-laws suggested by the Ministry, but they had not yet come into operation. They imposed a great deal of clerical work on the keeper of the home. It was most important to carry out the inspection without friction or annoyance and to choose the inspectors very carefully. The London County Council employed only medical officers and sanitary inspectors, as it felt that highly trained matrons might resent inspection from less well-qualified health visitors. Section 6 gave the local authority power to exempt institutions not run for profit. In London it had been considered wiser not to exempt all that came under this proviso, but to inspect them unless their work was already well known, as in the case of the smaller hospitals. Mental cases under single care technically came under this Act, but it had been decided at a conference between the London County Council and the Board of Control that as the patients were adequately visited by the latter body, and as it would be difficult to prove that nursing was provided, these houses should not be registered as nursing homes, provided there were no other nursing activities in them. The Council insisted that an isolation room should be provided wherever two or more maternity patients were housed in one room, and matrons were asked to state what steps they would take if a septic case occurred in a surgical ward or double room. Operating theatres were not required at present.

Dr. Hewat thought it would be quite possible to refuse certification on the grounds allowed in Section 1 (3). In London a provisional registration certificate was issued after the report of the various visitors had been received by the public health committee. Subsequent inspectors reported when the requirements had been complied with, and the final certificate was then supplied. Already there had been very considerable improvement, especially in cleanliness and general orderliness.

The Matron's Point of View.

Miss M. M. WINSTANLEY emphasised the fact that nurses had wanted the Act, and that their ideals were as high as could be desired; it was from no personal hardship that she offered certain criticisms of the requirements of the London County Council. For instance, they had thought it necessary to insist on outside staircases, balconies connecting with the next house, a certain number of exits; that area doors always be kept open, windows never be barred, and panels be lined with asbestos. Balconies connecting with the next house might cause considerable unpleasantness with neighbours, and area doors opening on to mews might cause grave nuisance. Matrons found it hard to believe that houses which they had been running for 30 or 40 years had suddenly become unsafe. They would not wish to put forward any argument against the safety of their patients, but they wished to ensure at the same time the safety of the patient and the safety of those women who had struggled for years and who depended on the homes for their livelihood. There was small danger of fire in nursing homes, owing to the constant supervision. No part of a nursing home was ever left unattended for long, night or day, and patients were safer there than in their own homes. Moreover, West End nursing homes were surrounded by fire stations and the record of fires in them was almost nil. On an average two-thirds of the patients in a home at any time would be well enough to walk out, and if sufficient extinguishers were provided the fire would soon be got under control. Nowadays there were very efficient fire escapes suitable even for abdominal cases. It was difficult to see how doors were going to be a protection; they made increased work and noise and liability to accidents, and it was more difficult to move patients and to detect fire by

smell. Nor could the nurse hear at once if patients got out of bed. Unbarred windows and open doors would be a danger to patients with high temperatures, who were apt to wander about. Demands for extensive structural alterations came very hard on people with short leases; fortunes were not made out of nursing homes nowadays, and nearly all the profits went into improvements. Matrons had felt that it would be helpful if someone with experience of running a nursing home could be consulted about equipment, staff, rooms, and such matters. Some medical cases, like pneumonia and typhoid, required larger rooms than surgical ones. Nursing could be magnificent without modern appliances, and the details of the running of a home must radiate from the personality of the head and her staff.

Discussion.

Dr. GERARD TAYLOR asked what was a reasonable standard of space to demand for a children's convalescent home. Standards ranging from 45 to 77 sq. ft. had been put forward by different authorities. In Berkshire they had made it a general rule not to grant exemption to any convalescent homes; this avoided invidiousness, and was working well.

Dr. R. M. F. PICKEN said that most of the trouble was going to arise out of the by-laws. Cardiff had adopted the model supplied by the Ministry, and difficulties had been raised by consulting surgeons. The local division of the British Medical Association had asked the Headquarters Staff of the B.M.A. to see the Ministry of Health with a view to altering these regulations. They objected, for instance, to compelling the keeper to enter every payment made by or on behalf of patients, on the grounds that it was no business of the local authority if the nursing home made a private arrangement with the doctor to take a poorer patient for a reduced fee. One surgeon had objected to the matron keeping medical records and had forbidden her to keep any of his cases, on the ground that he kept them himself. In this case the surgeon was the culprit, but the matron would be the person to be punished, and she was placed in a very difficult position. Objection was also made to requiring the keeper to record payments to any medical practitioner, although this was really intended to prevent the abuses of "farming out" and arranging to dispose of unwanted children. Cardiff had taken the line that only medical officers should visit any nursing home, except that the senior health visitor had been approved to inspect some of the small maternity homes.

Dr. STELLA CHURCHILL said that the Act had revealed an appalling state of affairs, and the future was going to be worse unless there was some alternative to the private nursing home. The necessary alterations could not be put into practice by many of the homes, and they would cease to exist. Paying wards in hospitals were over-full, and large paying hospitals were needed. The Bill had raised the standard and would also increase the shortage of nursing homes.

A vote of thanks to the speakers was proposed by Dr. CHARLES PORTER, and seconded by the PRESIDENT, who remarked that the Act, although very incomplete, had already been abundantly justified.

Dr. BUCHAN, in reply, said he was very glad that the London County Council was acting as it was, but he thought the time would come when it would realise that its interpretation was not justified by the Act. Nursing homes were not profitable concerns, and sympathy with their owners should be shown in drawing up requirements.

Dr. HEWAT, in reply, said he had found the entry of payments very useful in disputes between keepers and patients about fees. The by-laws had been approved by B.M.A. headquarters before being sent out. The cheap nursing home was going to suffer, but those that went would not be missed, as it was impossible to provide proper nursing attention at three guineas a week. The Act would not close down the decent home.

Reviews and Notices of Books.

THE BRAIN FROM APE TO MAN.

By FREDERICK TILNEY, Ph.D., M.D., Professor of Neurology, Columbia University. With Chapters on the Reconstruction of the Grey Matter in the Primate Brainstem by HENRY ALSOP RILEY, A.M., M.D., Associate Professor of Neurology in the University. In two volumes, with 557 illustrations, many in colour. London: H. K. Lewis and Co., Ltd. 1928. Pp. 1120. 5 guineas.

IN two superbly printed and illustrated volumes Prof. Tilney has made a contribution to the study of the evolutionary aspects of the central nervous system on a scale never previously attempted. The book is largely devoted to the technical side of comparative anatomy, as far as the brain is concerned; it is based on the view that minute comparison of the morphology of that organ in different representatives of the higher mammals is calculated to illuminate differences in behaviour among them as well as between them and man. At the same time a study of this kind will accentuate and explain the relative resemblances among the primates. Some 15 years of the author's life have been occupied with the anatomical preparation of material from no less than 11 of the higher mammals, beginning with the lemur and inclusive of gibbon, orang, chimpanzee, gorilla, and man. In each the whole brain has been examined macroscopically and microscopically; its measurements have been taken and its salient features recorded; the research has ranged from the fissural pattern of the cortex to the minute anatomy of the brain-stem. The accounts are fully illustrated with photographs of microscopical sections as well as with ingenious coloured reproductions of the relative size and position of the various ganglionic collections of grey matter in the pons, mid-brain, and medulla. Preceding each description is a succinct narration of the habits of the animal concerned; at the end of the sections are summaries with interpretations and discussions of the behaviouristic and anatomical data in their bearing on the evolution of the primates.

In the midst of this almost overwhelming anatomical profusion the distinguished author has not lost sight of his goal, which is to show that analogies outstrip differences, and that graded advances up the scale to man correspond to definite changes in structure which illustrate in unmistakable fashion the reality of the evolutionary process. The first volume, as a fact, really paves the way to the still more fascinating second volume, in which are chapters dealing with primitive and prehistoric man, with his cranial relics, and with the reconstruction therefrom of his types of brain. It is worth noting that Prof. Tilney sees in the progressive development of the functions of the hand that stimulus to increasing intricacy and complexity of structure which characterises the successive changes in the morphology of the brain; and it is curious to think that in this respect he has followed, one century later, the speculations of Sir Charles Bell. He does not hold with those who assert that man has descended (or, better, ascended) from an anthropoid stock; rather does the evidence point to the existence of a common pre-human stock, at some infinitely distant period, from which both anthropoid apes and man have, separately, come. Five distinctions between the two constitute fundamental divergencies—viz., the human brain, the human foot, the human hand, the erect posture with bipedal locomotion, and a terrestrial mode of life. A natural corollary of such studies is the question whether evolution is at an end; to this a negative if speculative answer is given. Man has within himself a "structural plasticity for further development" which has been sacrified in the case of the apes. The more organised the encephalic patterns the less are they capable of modification; variations

are the very basis of advance. Prof. Tilney allows himself the pleasure of meditating on the future of man, which he thinks lies with the frontal lobes.

THE MATRIX OF THE MIND.

By FREDERIC WOOD JONES, Professor of Physical Anthropology, University of Hawaii; and STANLEY D. PORTEUS, Professor of Clinical Psychology in the University. Honolulu: University Press Association.[1] 1928. Pp. 457.

THIS book adds still another to the increasing number of volumes of recent years which incorporate more or less successful (or unsuccessful) attempts to blend the subject matter of the sister sciences—neurology and psychology. The appearance of these is doubtless a favourable portent, as the authors remark, even if psychological purists still write as though the mind were no more closely connected with the brain than with the larynx; and even if the central nervous system is studied by many neurologists in almost total disregard of its higher functions. Of course, certain prolegomena are requisite if the two aspects of function are to be usefully correlated; working hypotheses must bridge gaps, and assumptions are essential to take the place of what is not proven and may never be. The actual handling of the material in the book, though we are in sympathy with the general viewpoint of its writers, is puzzling. The first part provides a compendium of physiological anatomy, human and comparative, which is interesting in itself and embodies not a few relatively little known data; but the information is sometimes rather obscured by an expansive style and an unusual resort to rather elementary illustrations which make us wonder for what class of readers the work is really intended. This impression is not lessened by the titles of some of the sections: "The triumph of the pallium," "Mistakes in brain building," "What the cortex cannot do," doubtless represent the truth, but they do not appeal to the tutored mind. It is curious that these methods should be used, for the physiology of the first part is not only thoroughly modernistic, but is excellently expounded with an eye to its bearings on, and relations to, psychology. The second part is similarly unconventional, though it is none the worse for that; we read of "Built-in habits," "Neural crossroads," "Sense of aliveness" with relish, mildly tempered by an undercurrent of methodological criticism. Yet here again the facts are well set forth and their trend indicated with conspicuous fairness.

A number of useful illustrations and diagrams are supplied, but there are no bibliographical references.

ŒUVRES DE PASTEUR.

Edited by P. VALLERY-RADOT. Vol. V., *Études sur la bière.* Paris: Masson and Co. 1928. Pp. 361. With 12 plates and 85 text-figures. Fr.120.

PASTEUR did not care much about beer himself but his patriotic spirit was so moved by the events of 1870 that he set to work enthusiastically to find out how the French brewers might make something as good as the German product which was at the time incontestably superior and had a European reputation. Applying the principles which he had already established, he showed that all that was needed was cleanliness and protection from contamination with undesirable microbes. His studies culminated in his "Études sur la bière" published in 1876 (an English translation in 1879), and the greater part of this volume of his collected works is occupied with a reprint of this classic. It is, of course, of much more than technical interest and contains many of Pasteur's proofs that micro-organisms are real things, arising from similar organisms and having specific fermentative reactions. Pasteur visited English breweries in 1871 and there is included some correspondence with Tyndall and Lister.

DENTAL ANATOMY.

Notes on Dental Anatomy and Physiology and Dental Histology. Fifth edition. By T. W. WIDDOWSON, L.D.S., Lecturer on Dental Anatomy and Physiology at King's College, London. London: John Bale, Sons, and Danielsson. 1928. Pp. 588. 25*s*.

THIS book was designed as a note-book for students preparing for examinations, to be read with larger and more formal text-books. In successive editions the size of the volume grew, but its character was retained. But in this fifth edition the scope of the book has been changed, and it has been transformed into a text-book of dental anatomy, which competes with such well-known works as those by Tomes and Mummery. It is a pity that the author has still retained a misleading title which does not now do justice to the contents of his book. While it does not contain the wealth of detail on comparative dental anatomy which has made Tomes's book so valuable to the serious student of zoology, or the original work on dental histology which distinguishes Mummery's treatise, it provides an extremely well-written and clear account of a subject which the average dental student usually dreads. The author has shown much skill in selecting the relevant points from the material at his disposal, and in giving the student the information essential for examination purposes. The opening chapters on cytology and embryology form a useful introduction, which is followed by an excellent account of the development of the jaws in which the work of J. C. Brash and E. Fawcett is fully described. The difficult subject of the evolution of tooth forms is successfully described, especially the complicated theory put forward by L. Bolk. The chief value of the book lies in the skilful way in which controversial points which might confuse the dental student are dealt with. The author deserves congratulation on an admirable production.

NARCOTIC POISONS AND ADDICTION.

Rauschgifte und Suchten. By Dr. FRITZ REDLICH. Bonn: Kurt Schroeder. 1929. Pp. 98. M.4.40.

IN a booklet of 98 pages, with numerous statistical tables and copious bibliographical references, Dr. Redlich reviews the world production and consumption of cocaine, opium, morphine, and heroin, literally and specifically from China to Peru. Figures are cited to show that, alike in the old world and in the new, cocaine has since the war become a more potent factor than formerly in the production of mental disorder, as well as in its illicit employment for vicious and criminal purposes.

The story of opium cultivation in China is told: its almost complete cessation in the years following the arrest of export to China of Indian opium from 1907 onwards, and the recrudescence of opium-growing during the civil wars. The method of Government monopoly of opium production and distribution in India is described; the continued export of Indian opium to eastern countries, other than China, and the large consumption of opium in certain townships in India and Burma are commented upon. The manufacture of morphine is, according to the available statistics, enormously in excess of any conceivable requirement for medicinal purposes. The amount of the drug, either licitly or illicitly imported into China—if the figures vouchsafed can be relied on—is appalling; from 1917 to 1920 20 to 30 tons are recorded as having been annually imported or smuggled into that country. The best that can be said for the morphinomaniac, according to Dr. Redlich, is that his criminality is more passive and less dangerous

[1] Messrs. Edward Arnold and Company inform us that they have taken over the British Empire and Continental rights of this book and that orders for it should be sent to them. A revised edition (probable price 21*s*.) is in the press and will be ready before Easter.

than is that of the victim of cocainism. As regards heroin, prior to the Great War Germany had practically a monopoly of the manufacture of this alkaloid, but since the war Great Britain, Japan, Switzerland, and the United States have engaged in its production, but in the last-named the manufacture and importation of heroin has, since 1924, been forbidden by law. At the second Geneva Opium Conference such restriction, though advocated by the American delegation, was opposed by the French, German, and English representatives, who considered heroin to be an indispensable drug. Dr. Redlich regards 1½ tons of heroin annually as adequate for the world's supply for medicinal purposes. He confirms the view that heroin is the most pernicious and insidious of all narcotic drugs in its mental and moral effects.

In his final chapter Dr. Redlich discusses the problem of combating narcomania in its various manifestations. He agrees that the plan urged by the American delegates at Geneva, and adumbrated by the British delegates at The Hague Conferences—viz., limitation of production at the source of the raw materials and manufacture of drugs of addiction—would be successful, if only it were practicable. The alternative method advocated by Germany and supported by some other States, of an international syndicalisation of the drug traffic, is not free from objections. Questions would arise as to which countries should be the producers, and also as to the price to be charged, medical needs requiring a low one and the monopoly a high one. The author believes advance must be gradual, and by way of strict control of the manufacture and of the channels of distribution of dangerous drugs, and that this requires international coöperation of the police and heavy punishments for offenders in the matter of illicit traffic or consumption.

TRIAL OF EUGENE MARIE CHANTRELLE.

Edited by A. DUNCAN SMITH. Edinburgh and London: W. Hodge and Co, 1928. Pp. 243. 10*s*. 6*d*.

Chantrelle, a Frenchman teaching languages in Edinburgh, made a hasty marriage with one of his school-girl pupils who was only 16 when the first of their four children was born. She was a good wife, he a violent, cruel, and unfaithful husband. Finding his financial position difficult, his professional work falling off, and his debts increasing, he insured her life (in spite of her objections and to her manifest alarm) for £1000 against death by accident. On New Year's Day, 1878, she was alive and well; next morning the servant found her unconscious in bed. Chantrelle sought to suggest that she was poisoned by coal gas; he apparently tampered with a gas-pipe himself after his wife lost consciousness. Dr. James Carmichael was summoned; he sent for Dr. H. D. Littlejohn, the city medical officer, telling him there was a case of gas poisoning for him to see. Mrs. Chantrelle was removed to the Royal Infirmary where she died without recovering consciousness. At the infirmary Prof. Maclagan was strongly of opinion that the poisoning was not from gas, but from some narcotic. Post-mortem examination confirmed the view that gas had not caused death, but failed to prove the presence of a narcotic; subsequent chemical analysis of parts of the body gave no positive result. On Mrs. Chantrelle's night-dress and bedding there were stains of vomit in one of which opium was detected. The evidence against Chantrelle was circumstantial. He had dabbled a good deal in drugs and had a cupboard full of bottles, some of which contained opium. He had threatened to take his wife's life; he had the means and the opportunity; he had no affection for her; he had a strong financial motive for murder; his behaviour over the gas escape was highly suspicious. The jury having found him guilty, he made an injudicious outburst in which he seemed to throw over the gas poisoning theory and to accept the evidence of opium, thus weakening his previous defence.

Medico-legal readers of the trial will form their own opinion whether modern scientific evidence would not have been more conclusive. The medical witnesses 50 years ago had seen few cases of coal gas poisoning. Mr. A. Duncan Smith has edited the trial with such thoroughness as to include a full description of Chantrelle's last hours and execution. In his editing he was appropriately assisted by Emeritus Professor Sir Henry D. Littlejohn. The present Lord Shaw, it is interesting to note, was one of Chantrelle's counsel. The book first appeared in 1906 in the Notable Scottish Trial Series. Uninstructed English readers might have been glad of some brief note on Scots law phraseology and the distinctive features of Scottish procedure such as the absence of a coroner's inquest and the omission of an opening speech for the Crown.

PROTOZOA.

Lehrbuch der Protozoenkunde. Founded by FRANZ DOFLEIN. Fifth edition. Revised by Prof. Dr. EDUARD REICHENOW, Departmental Director at the Institute for Marine and Tropical Diseases, Hamburg. Part II., *Spezielle Naturgeschichte der Protozoen*. First half: *Mastigophoren und Rhizopoden*. Jena: Gustav Fischer. 1928. With 435 text-figures. Pp. 326. M.22.

PART I. of the fifth edition of this well-known treatise on protozoology was reviewed in THE LANCET, 1928, i., 914. It dealt with general principles without any special reference to parasitic forms, though these received ample consideration. The first half of Part II. begins with the classification of the protozoa and discusses in detail the mastigophora and rhizopoda, concluding with a classification of the sporozoa which, with other groups not dealt with in this section, will form the subject matter of the second half of Part II.

Prof. Reichenow has adhered to the arrangement of the original author, Franz Doflein, but much new matter has been introduced, particularly in connexion with parasitic forms which produce disease in man and animals. In this respect the present edition is a distinct improvement on the earlier ones, in which the human parasitic protozoa received inadequate attention. Now, however, the protozoologist will find in it a clear and accurate account of these important organisms, and the work has thus become as useful to the medical man and veterinarian as to the zoologist. The protozoa are subdivided into Doflein's two main groups, the plasmodroma and ciliophora. The former, with which the first half of Part II. is mainly concerned, is subdivided into the classes mastigophora, rhizopoda, and sporozoa, the mastigophora preceding the rhizopoda as representing the more primitive forms. The subject matter is handled in the careful manner which we expect from the authors. When the work is completed the library of protozoologists will be enriched by a comprehensive treatise, beautifully and profusely illustrated.

FROM THE MONOTREMES TO THE MADONNA.

By FABIUS ZACHARY SNOOP. London: John Bale, Sons, and Danielsson, Ltd. 1928. Pp. 143. 3*s*.

THIS little book claims to be a study of the breast in culture and religion. In spite of its alliterative title and certain tricks of style which may irritate some readers, the book is obviously the work of an extremely well-read person. It seeks to prove that the ideas which surround the breast in folk-lore, literature, and art lead to fundamental characteristics of religious belief and human behaviour. Perhaps the most interesting chapters are those on Aaron's Breastplate and the significance of jewellery worn on the breast, on Mountains of Myrrh, dealing with the art of and reasons for perfumery, and the Bloody Teat, on injuries of the breast inflicted in the interests of culture. Some of the author's ideas and opinions, though interesting, will not meet with general acceptance.

JOURNALS.

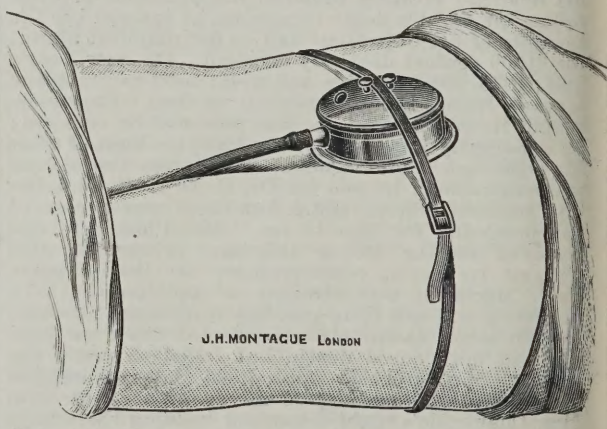
JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXXII., pp. 1–172, January, 1929. — Focal Necrosis of the Liver, by J. W. Edington (Sheffield). The characteristic change found in guinea-pigs infected with *Bacillus aertrycke* may be reproduced by tying the common bile-duct and injecting various organisms or toxins subcutaneously. The lesions are localised by biliary stasis.—Chronic Peptic Ulcer of the Œsophagus, by M. J. Stewart and S. J. Hartfall (Leeds). Epigastric pain and recurrent hæmatemesis; death from perforation into right pleura.—"Smooth-rough" Variation in Bacteria in its Relation to Bacteriophage, by F. M. Burnet (London).—Retro-peritoneal Ganglionic Neuroma, by D. F. Cappell (Glasgow). A very large tumour composed of adult ganglion cells and nerve-fibres and correspondingly benign.—Three Notes on Tuberculin, by H. J. Parish and C. C. Okell (London). Tuberculins are very stable and heat-resistant. Skin sensitiveness develops in guinea-pigs in a week after infection.—The Relationship between the Hæmolytic Complement and the Opsonic Power of Normal Guinea-pig Serum, by J. Gordon, H. R. Whitehead, and A. Wormall (Leeds). Destruction of hæmolytic complement by ammonia does not greatly reduce the opsonic power of the serum.—The Nervous System in Rats Fed on Diets Deficient in Vitamins B 1 and B 2, by R. O. Stern and G. M. Findlay (London). Absence of both factors or of the antineuritic factor does not cause any specific lesions in the nervous system despite the occurrence of paralytic symptoms. Absence of B 2 produced symptoms and skin lesions like pellagra with vacuolation and pigmentation of motor cells in the cord.—A Case of Diabetes Mellitus with Acromegaly and Lipæmia, by J. Gray (Aberdeen). Death from diabetic coma: cirrhosis of pancreas, chromophobe adenoma of pituitary.—The Isolation of *Bacterium morgani* from the Mammals, Birds, and Reptiles at the Zoological Gardens, by R. Lovell (London). Morgan's bacillus seemed to be the cause of death in four monkeys, one bird, and four reptiles.—Notes on Intestinal Bacilli, with Special Reference to Smooth and Rough Races, by P. B. White (London). Rough races probably afford the better basis for a rational classification.—Diffuse and Nodular Fibrosis of Adventitia of Aorta, by W. G. Barnard (London). A remarkable overgrowth of the adventitia up to 10 mm. thick of dense fibrous tissue, probably rheumatic.—Generalised Vaccinia in Rabbits with Especial Reference to Lesions in the Internal Organs, by S. R. Douglas, W. Smith, and L. R. W. Price (London). A condition resembling alastrim may be produced in rabbits in which almost all the organs except the kidneys show lesions. Virus may remain latent in the tissues for as long as six weeks after infection.—Standardisation of Antidysentery Serum: Effect of Increased Test Dose on the Accuracy of the Titration, by A. V. Blake and C. C. Okell (London). A considerable increase in precision is obtained by using five times the usual test dose of bacillary bodies.—A Statistical Note on the Testing of Antidysentery Sera, by J. W. Trevan (London). Statistical discussion of the preceding paper generally applicable to such experiments.—Siderosis of the *Globus pallidus*: Its Relation to Bilateral Necrosis, by G. Hadfield (London). The blood-vessels of the *Globus pallidus* are often degenerate and encrusted with iron salts (formerly described as "calcification"); this explains the bilateral necrosis often found in CO poisoning which is not immediately fatal.—Experiments on the Nature of the Carcinogenic Agents in Mineral Oils, by C. C. Twort and J. D. Fulton (Manchester). The active agents are concentrated in extracts made with methyl sulphite, methyl sulphate, or picric acid, and rendered inactive by treatment with sulphuric acid or silica gel, and by oxidation or reduction.—Neuroglial Tumour of Spinal Cord, by W. G. Barnard (London).—A Simple Method of Preparing Accurate Pen and Ink Drawings of Specimens, by T. Shennan (Aberdeen). An ordinary photo print is inked in as desired with India ink and bleached with iodine and "hypo."—Generalised Osteosclerosis, by F. Parkes Weber (London). A typical example of marble bones with severe anæmia.—Demonstration of the Peculiar Bodies of Pulmonary Asbestosis in Material Obtained by Lung Puncture and in Sputum, by M. J. Stewart and A. C. Haddow (Leeds).

THE Published Papers by Members of the Staff of the Middlesex Hospital Medical School for the year 1927–28 have been issued in the usual form of a collection of reprints of various shapes and sizes bound in one volume. Most of the papers have already been published in widely circulated journals and need no further reference. An address delivered at the Lake Mohonk Conference on Cancer Control in May, 1927, by Mr. Sampson Handley, here reprinted, gives an interesting account of the development of cancer education in this country. Dental research is represented by an important paper by Mr. Warwick James and Dr. A. Counsell on the primary lesion in so-called pyorrhœa alveolaris, and by a paper by Dr. Lazarus Barlow on the bacteriology of the alveolar bone in relation to pyorrhœa. The physiological department is responsible for many interesting papers, especially one on the ethyl iodide method for the estimation of the circulation rate in man by Dr. Samson Wright and Mr. M. Kremer. An outstanding contribution from the pathological side is the article by Mr. D. H. Patey and Dr. R. W. Scarff on the position of histology in the prognosis of carcinoma of the breast, reprinted from our own columns. A lecture on the ovarian hormone by Prof. E. C. Dodds sums up a large amount of work by himself and his colleagues in the Courtauld Institute of Biochemistry.

New Inventions.

AN IMPROVED BOX FOR USE AFTER SUPRAPUBIC CYSTOTOMY.

THE box shown in the illustration is an improvement on the old Hamilton Irving box which is wrong mechanically. The latter consists of an oval box which has to adjust itself to a convex or concave surface; to this end it is held by four straps, which can never maintain an equal tension; with each movement the



patient tightens one at the expense of the rest, and this results in displacement of the box and causes leakage. The new box consists of a section of a sphere fixed at its top central point (by a single band of half-inch elastic), so that pressure is distributed equally to every part of the rim. Thus, with every movement of the patient the sphere of the rim adjusts itself mechanically to the convex (or concave) surface of the abdomen.

The boxes are made for me by J. H. Montague, 69, New Bond-street, London, W.

SYDNEY G. MACDONALD, M.B., B. Chir. Camb., F.R.C.S. Eng.

THE LANCET.

LONDON: SATURDAY, JANUARY 26, 1929.

THE KING'S HEALTH.

THE announcement on Tuesday last by HIS MAJESTY'S doctors that the time was approaching when the patient might be removed safely to the South Coast has been regarded widely as a landmark in the long story of the illness. Although the public has been expressly warned that the period of convalescence cannot yet be regarded as having set in, it is highly reassuring to note that the KING'S medical advisers can contemplate for him a somewhat lengthy journey by road or rail in the immediate future. The place of residence has been chosen for its close proximity to the sea, its southern exposure, and its protection from wind, while the location is associated with a measure of privacy and provides reasonable access to London. Bognor is regarded as one of the sunniest of the South Coast health resorts. Its rainfall averages under 26 inches in the year, and there is but little fog or frost, while in the commencing Spring the north-easterly winds are kept off the seaboard by the nearness of the South Downs. The mean temperature of the winter months is about 42° F., and there is an average of 2·8 hours of sunshine a day, being about 30 per cent. of the possible hours during which the sun is above the horizon. Craigweil House, which has been lent for the reception of the KING by Sir Arthur Du Cros, has been extensively altered since it was used by the late Dr. A. H. Stocker as a convalescent station for his London patients, and the large grounds, gently falling to the strand, afford ample scope for exercise and for the assistance to convalescence under conditions of perfect privacy. Craigweil House not only enjoys a full South exposure, but has been equipped with rooms specially designed for sun treatment. The stimulating quality of the sea air is likely to be helpful, both in its generally invigorating qualities and in its special aid to the restitution of damaged tissues. The empyema wound is now stated to be small and steadily healing, and the relative unimportance of this complication may be gauged by the fact that twice during the past week Sir Hugh Rigby has not been asked to sign the official bulletin. Under such conditions we may reasonably hope that convalescence may soon be reached. Especially encouraging is the announcement that solid food is now being enjoyed, for it is an open secret that for a long time it required HER MAJESTY'S constant assistance to ensure that nourishment of any kind was taken.

Once again we may congratulate the KING'S medical advisers on the fruition of their devoted labours, and on having found in the Royal household so ready an acceptance of the measures which they considered desirable to employ. It is generally believed that nowhere can better treatment be found than in one of the large general teaching hospitals of London, but HIS MAJESTY'S wonderful recovery may lead to a justifiable suspicion that in one household these conditions have been bettered. The KING'S health will still take the central place in the interest of his subjects, though all the indications are that the story will now be uneventful even if prolonged.

TONSILLECTOMY FOR ARTHRITIS.

THE part played by the infected tonsil in the production of chronic disturbance in distant-lying organs is being closely studied in this country and in America. In setting out recently [1] some of the evidence for this belief, it was remarked that the culpability of the tonsil is not easy to establish in the group of conditions generally called rheumatic. A. D. KAISER, of Rochester, N.Y., in examining the records of 48,000 school children, found [2] that the incidence of rheumatic fever and joint pains was slightly less in the 20,000 whose tonsils had been removed than in the remainder in whom they had not been removed, and some earlier work at the Mayo Clinic aimed at assessing the effect of tonsillectomy performed after subacute joint trouble had already set in. This week, in our own columns, Mr. A. B. PAVEY-SMITH, of Harrogate, records an analysis of the results of tonsillectomy performed at the Royal Bath Hospital there. Of the 7000 cases of arthritis and allied diseases treated at this hospital in the six years under review, some 400 were sent to Mr. PAVEY-SMITH on account of conditions falling under the three headings of subacute rheumatism, chronic infective (focal) arthritis, and fibrositis. From these he chose about 200 of ages ranging from 10 to 64 as suitable for tonsillectomy, which was accordingly performed. His observations on them lead him to think that a probable tonsil focus can be found in a large number of cases falling into these three groups, and he says that when the tonsil is removed the results are so good in one group—namely, subacute rheumatism—that tonsillectomy should become a routine part of its treatment if only as a prophylactic against recurrence and cardiac complication. He claims that even when septic tonsils have caused chronic inflammation in joints improvement from their excision may be expected in 80 per cent. of cases, provided that the tonsil actually shows one or other of the stigmata of infection. He admits, however, that systemic infection can never be deduced from the appearance of the tonsil itself; it can only be inferred. We regard Mr. PAVEY-SMITH'S observations as worthy of record and his figures as distinctly favouring the conclusions which he draws. His cases had the merit of being taken serially, although they lack comparison with a control group of similar cases treated without operation and watched for a similar length of time. It may be that no such valid control is obtainable, but it would be of interest to follow up the 200 other patients who were referred to him on account of focal sepsis and in whom he failed to find enough evidence to justify tonsillectomy. The class of case included in the series is so common and so distressing in its disability and chronicity that the success of so simple a remedy would be very heartening to the practitioner who may be overwhelmed by the number of such cases and his comparative helplessness in the face of them. Apart from the clinical evidence in his paper, Mr. PAVEY-SMITH adduces evidence which increases the suspicion under which the *Streptococcus viridans* already lies as the primary infective agent in chronic focal arthritis. The occurrence of the organism is, in fact, so frequent as to imply that it must either be an active agent or count for nothing at all. In this matter any effective control might be still more difficult to devise.

YELLOW FEVER.

TWENTY-EIGHT years ago WALTER REED'S Cuban Commission proved that yellow fever is spread by mosquitoes, and after a campaign of 90 days the city of Havana was freed from infection for the first time in 200 years. It then seemed that the disease had ceased to be a major menace to life in the American and African tropics; it seemed that the victory of scientific method was complete and that scientific tactics would shortly clear the danger zones of all their smouldering infection. But while these hopes have been largely realised in America we are faced in West Africa with a situation that grows more threatening with every new facility for rapid transport. Yellow fever still lingers in the colonies and protectorates up and down that coast, and its presence has become important to sanitarians of other countries because it is now within the bounds of possibility that the virus may be disseminated among mosquitoes in distant parts of the world. Not only is the ordinary vector—*Aëdes aegypti* (*Stegomyia fasciata*)—found throughout the tropics and sub-tropics, but it has been shown that other mosquitoes even of a different genus are capable of carrying the disease. The shortness of the time of incubation is no longer a certain obstacle to the passage of infected persons across the African continent, and it is feared that yellow fever may travel by relays into the Orient just as once it may have travelled to America by way of slave ships. So, in Sir WALTER FLETCHER'S words, "It is no stretch of fancy to say that the discovery of the true nature of the disease and of its preventability by vaccination may have come just in time to save us from a world disaster of unthinkable magnitude." Yellow fever investigators, as he says, are playing for high stakes, and this is the justification for the hazard of so many valuable lives.

Those who know the story of WALTER REED'S researches will recall that the members of his Commission risked not only their own lives but also those of many volunteers whose names and deeds have mostly been forgotten. Deaths from yellow fever among the American troops in the Spanish War had far outnumbered the fatal battle casualties, and REED was clearly right in deciding that it was worth while to make further sacrifices if thus and thus alone it could be discovered how to prevent the disease. But once the main problem of transmission had been solved and the emergencies of war were over, it was impossible for his successors in research to experiment with human beings where so deadly an infection was concerned. The odds were thus against them, for almost all attempts failed to transmit the virus to monkeys, dogs, rabbits, guinea-pigs, or other animals, and all these possible hosts were found unsatisfactory for practical purposes. As is well known, NOGUCHI reproduced in guinea-pigs a condition which he regarded as identical with yellow fever and which he said was due to the *Leptospira icteroides*. For many years, indeed, this held the field as the causal organism of yellow fever, and was used extensively in the manufacture of vaccines; but we now know that it in no way differs from the *Leptospira ictero-hæmorrhagiæ* of Weil's disease and must attribute the confusion to erroneous clinical diagnosis or to coexistence of the two infections in certain cases. Controversy over the significance of the leptospira gave rise to suggestions that African and American yellow fever were not the same disease, and these and other doubts and difficulties could not readily be solved as there was no animal on which to make the necessary tests. Hence we may say that the renaissance of yellow fever research dates from 1927 when ADRIAN STOKES, J. H. BAUER, and N. P. HUDSON discovered that Asiatic monkeys, notably the *Macacus rhesus*, are susceptible to the virus. Previous experiments with African monkeys had always failed, but it has now been ascertained that several species of macacus, including *cynomolgus*, can be used for laboratory studies. The work undertaken by STOKES and other members of the Rockefeller Commission at Lagos at once confirmed the statements of REED'S and MARCHOUX'S commissions by proving that yellow fever virus will pass through V and N grades of Berkefeld filters. Infected organs were found to retain their virulence for at least 18 days if kept frozen—HINDLE claims, indeed, that liver or blood dried in vacuo will remain virulent indefinitely—and these discoveries have made it possible to start research on yellow fever in northern countries where natural infection is unknown and where the conditions of experiment are therefore easier. In March of last year Dr. A. W. SELLARDS, of Harvard University, brought to London the liver of a monkey infected from a patient at Dakar, and this strain has been the basis not only of HINDLE'S investigations but also those of A. PETTIT and others in Paris.

The latest news of Prof. EDWARD HINDLE'S studies is summarised on page 183, and our readers will see at once how fruitful they have been. Profiting by the knowledge of filterable viruses which has accumulated recently in this country from the study of dog distemper and fowl plague, he was able, on receiving yellow fever virus, to prepare a vaccine which is extremely potent in protecting monkeys against the disease. Last June he showed that phenolised glycerine emulsion of the liver and spleen of infected monkeys confers immunity against 10,000 to 100,000 lethal doses of the virus, and the preparation by which he has now superseded it is equally effective in protecting animals. Its value to human beings is, of course, less easy to assess, but there is every reason to suppose it considerable. A vaccine made according to a slight modification of HINDLE'S recipe has been tried at Rio de Janeiro by H. DE B. ARAGÃO, who has used it without ill-effects in 300 or 400 cases and has arranged for its preparation on a large scale by the Brazilian Public Health Department. Our own Colonial Office has also decided to give HINDLE'S vaccine a trial, and its employment in the West African colonies will be watched with deep interest.

Prof. HINDLE'S own experiences bear witness once again to the risk of working with yellow fever in the laboratory, and it now seems certain that the virus may enter the body not only by the bite of insects but also through mucous membranes and possibly even through intact skin. The fact that the serum of convalescents confers a transient immunity has been used by members of the Rockefeller Commission and others to protect those in close contact with the disease, and attempts are being made in PETTIT'S laboratory and elsewhere to prepare a serum strong enough to modify the course of the illness once it has begun. No such powerful remedy has yet been made, and for the present our hopes lie wholly in preventive measures. These must partly depend, however, upon the early recognition of incipient epidemics, and here the susceptibility of rhesus monkeys is of incalculable value. The blood of a

atient as a rule contains the virus during the first ree days of his illness, and its injection into onkeys should reveal the true nature of the fever, hilst the serum of a convalescent will confer an mmunity which is equally characteristic. This use monkeys will have to continue until some sero- gical reaction has been devised to take its place, and ese animals will have to be supplied without stint nce diagnosis followed by efficient vaccination is ir best means of combating the disease in places hich cannot at present be rid of the mosquito. is now understood that native populations have a gh resistance to infection, and that yellow fever curs among them in all forms from the very mild the severe and fatal; and the existence of cases hich are unrecognisable clinically is of course an er-present peril. But if they can be diagnosed rrectly and if (as we earnestly hope) HINDLE'S ccine is capable of immunising large numbers of ople without difficulty or danger, the problem of llow fever in Africa will be well on the way to lution, and we shall be able to wait with equanimity r further light upon the characteristics of the usal virus.

"MASTERLY INACTIVITY" IN THE TREATMENT OF SYPHILIS.

LAST week we gave an account of some Norwegian udies in syphilis which raise again the question of te neuro-syphilis in relation to the modern treatment the disease. The late CÆSAR BOECK, professor of rmatology in the University of Christiania (Oslo), ed to teach that the so-called specifics, potassium dide and mercury, are symptomatic remedies which ot only fail to eradicate the disease, but also paralyse ne body's natural defences, with the result that the isease runs an atypical course and inflicts serious juries on certain internal organs, particularly the ntral nervous system. The validity of this theory as tested by two of BOECK'S successors, Prof. BRUUSGAARD and Dr. S. DAHLSTRÖM, and the results f their investigations are very striking. Of 2181 atients suffering from primary and secondary yphilis who had attended BOECK'S clinic between the ears 1891 and 1910 and were treated by BOECK'S ethod of "masterly inactivity," only 0·6 per cent. eveloped general paralysis and half that number ffered from tabes. In the discussion which followed rof. BRUUSGAARD'S paper Dr. DAHLSTRÖM pointed ut that the commonly accepted computation of the equency with which cases of syphilis end in general aralysis is about 4 per cent., and that during the 3 years he had been practising as a psychiatrist he ad been on the look-out for paretics among BOECK'S d patients, but had found hardly any, whereas atients who had been treated with mercury frequently appeared with signs of general paralysis.

The whole question of the anti-syphilitic remedies as often been revived since the introduction of the ewer methods of treatment with salvarsan or one its many derivatives, and with bismuth. Many uthorities hold the view that this treatment has sulted in more cases of late neuro-syphilis, while ther equally competent observers maintain the verse, and affirm that many of the cases which do cur result from insufficient treatment of the disease its secondary stage. It is well known that unless aximal doses of the drug are given sufficiently often a course, and without too long an interval between ne courses, arsenic-resistant strains of the spirochæte ay develop in the body, and ultimately these may produce neuro-syphilis and other visceral lesions. In order to prevent this untoward event efficient treatment with mercury or bismuth is recommended either concurrently with the arsenic or subsequently, and between these combined courses the administration of large doses of iodides is advised. It appears that the modern antispecific treatment of syphilis is receiving somewhat of a check, for it is now recommended by some continental authorities that non-specific remedies—and notably malarial therapy, which has already achieved such remarkable success in the treatment of general paralysis—should be employed in the treatment of early syphilis. KARL ZIELER, who has recently written upon this subject,[1] is of opinion that malarial therapy is not a method suitable for general application and that it can only be used in hospitals. Moreover, he says, it does not always prevent subsequent neuro-syphilis, and it should only be used, he thinks, when ordinary treatment has failed to render the cerebro-spinal fluid Wassermann-negative.

The problem of the conflict between the invading spirochæte and the defensive mechanism of the invaded body, and the ultimate effect of our interference, either by the older methods of treatment with mercury and iodides or the newer methods with salvarsan and mercury or bismuth, is worthy of closer study. So far as we are aware there are no figures at all comparable with those of BOECK'S available in this or any other country, and it would probably be difficult in the present state of medical opinion to find practitioners bold enough to adopt BOECK'S method of treating syphilis by withholding all the recognised antispecific remedies and simply maintaining the patient's defensive mechanism. It should be possible, however, to follow up the after-histories of a specified group of syphilitic patients who had received adequate treatment with modern anti-specific remedies, with the view of ascertaining what proportion of these patients are showing signs or symptoms of late syphilis of the central nervous system or other viscera. L. W. HARRISON estimates that during the war 100,000 men in the Army received treatment for syphilis, but most of these, of course, are now absorbed into civil life and could not be traced. It should be possible, however, to follow up the cases which occurred in the Navy, and valuable information might thus be obtained by which an authoritative reply to this very important question could be given. Syphilis still presents many problems which in the present state of our knowledge (or ignorance) elude solution. Why is it that the disease as we see it to-day is so much less virulent than it was 30 or 40 years ago? Is it because we are becoming to some extent immunised or that the spirochæte is becoming attenuated, perhaps as the result of the modern methods of attack? How can we explain why (as sometimes happens) only one child in a family suffers from congenital syphilis, with healthy brothers and sisters older and younger than itself? Why is it that the mothers of congenitally syphilitic children, though they are usually Wassermann-positive, rarely give a history of primary or secondary lesions or indeed of any ill-health? What is the significance of the fact noted by P. C. JEANS in America, and DAVID NABARRO in this country, that 70 or more per cent. of the fathers of syphilitic children give a negative Wassermann reaction and often deny any history of infection or of treatment? It must be left to the future to furnish the answers to these and other important questions.

Annotations.

"Ne quid nimis."

VITAL STATISTICS FOR 1928.

THE Registrar-General has issued a provisional statement of the figures for birth-rate, death-rate, and infantile mortality during the year 1928.

—	Birth-rate.	Death-rate.	Infant mortality-rate.
England and Wales ..	16·7	11·7	65
107 county boroughs and great towns including London	16·9	11·6	70
156 smaller towns ..	16·7	10·6	59
London	15·9	11·6	67

The smaller towns are those with a population in 1921 of 20,000–50,000. The death-rate for England and Wales (which is based on the estimated population in 1928) relates to the whole population, but that for London and the two groups of towns (based on the 1927 estimate) relates to the civil population only. Birth-rate and death-rate are per 1000 population, infant mortality-rate per 1000 live births.

The Registrar-General remarks that the birth-rate is 0·1 per 1000 above that of 1927. The death-rate is 0·6 per 1000 below that of 1927 and only 0·1 per 1000 above the lowest recorded (1923 and 1926). The infant mortality-rate is the lowest on record, 4 per 1000 births below that of 1923. These provisional figures, which are not likely to require substantial modification, have been issued for the information of medical officers of health.

INTRAVASCULAR CLOTTING.

THROMBOSIS is stated to occur in something over one per cent. of all operations, and the same incidence seems to hold good for parturition. If the suggestion of F. de Quervain is accepted that a considerable proportion of the cases of post-operative pneumonia is due to the formation of thrombotic emboli thrombosis may be an even more common sequel of operation than is suspected. There is no indication that the incidence of post-operative thrombosis has diminished within the last 20 years. Indeed, in Germany it is stated to show a considerable increase since 1922. In any case the problem of the causation of this condition is of sufficient importance to arouse the interest of surgeons and obstetricians. The recent discussion on this subject by the combined sections of Obstetrics, Surgery, and Pathology of the Royal Society of Medicine, of which a report is given in another column, has shown that clinical evidence is unable to throw much light on the problem and that its solution must come from the laboratory. Indeed, the most important contribution to the discussion did come from the laboratory in the opening remarks by Dr. W. Howel Evans. The observations of Dr. Evans and his collaborators have recently been published,[1] and were then the subject of a detailed review in our columns.[2] It is, therefore, only necessary to state briefly that in a large number of operations a great increase in the number of blood-platelets was found to occur after the operations, and the same was observed after childbirth. The rise begins about the fourth day, increases to a maximum about the tenth day, and then falls slowly back to the normal level. The rise in the platelet count was accompanied by a shortening of the coagulation time of the blood when measured outside the body. It is remarkable that, clinically, thrombosis occurs most frequently at about the time that the rise in the platelet-count reaches a maximum. It must be noted that none of the surgical cases in which the platelet counts were made developed thrombosis. Dr. Evans expressed himself very cautiously in appraising the significance of this new and important observation, and it is clear that further investigations are necessary to determine whether a platelet rise above a certain limit is in itself sufficient to induce thrombosis or whether additional factors are involved in it. But his work has opened up a way of attacking at least one aspect of the problem by experimental methods. By performing operations on animals it may be possible to determine the factor, or factors, responsible for the post-operative rise in the blood-platelets. The suggestion by Mr. D. H. Patey that stasis of the circulation plays an important part in the onset of thrombosis seems well founded. It is important from the practical point of view, because it offers a means of preventing thrombosis by avoiding conditions favouring stasis. On the other hand, the suggestion made by another speaker of injecting anticoagulants would hardly be justified in the light of our present knowledge of the mode of action of these substances. The action of such a substance as heparin is transient, lasting only for a few hours, and is followed by a reaction in the opposite direction, as a result of which the coagulability of the blood is increased.

It may seem curious that the ætiology of thrombosis is so little understood when the physiological literature on blood coagulation fills literally volumes. But as pointed out recently by Dr. J. W. Pickering in his excellent monograph,[3] "The Blood Plasma in Health and Disease," physiological and biochemical work on blood coagulation is, with very few exceptions, characterised by a disregard of the blood-platelets. Indeed, in this country, with the single exception of the Edinburgh School of Physiology where, under the influence of Sir Edward Sharpey-Schafer, histology has been taught as an integral part of physiology, and where the work of W. Cramer and of J. Tait has demonstrated the important part played by the platelets in blood coagulation, physiologists have categorically denied the presence of blood-platelets as living cellular elements existing in the circulating blood. It is to be hoped that this discussion, by emphasising the importance of the blood-platelets in the ætiology of an important pathological lesion, will help to remove this erroneous teaching and stimulate further research into the physiology of the blood-platelets.

THE CENTRAL ASSOCIATION FOR MENTAL WELFARE.

IT is characteristic of our country that much of the best and most of the pioneer social work is carried out by voluntary bodies which are remarkably efficient and well organised. An example of fine voluntary work for the public health is afforded by the Central Association for Mental Welfare (C.A.M.W.), which continues to point the way to long-overdue legislation for the subnormal population. The Mental Deficiency Bill passed through Parliament at the end of 1927 largely owing to the unremitting efforts of the Association's members. During the following year work was organised in three areas where the local authorities have not been able to administer the Mental Deficiency Act, and central organisers stayed in the districts until a local organisation was well established. A valuable department of the work is the educational courses provided for all whose work brings them into contact with defectives. The report states that it is increasingly difficult to find experienced and competent people to fill administrative teaching and nursing posts as they fall vacant

[1] Jour. Path. Bact., 1928, xxxi., 883.
[2] THE LANCET, 1928, ii., 982.
[3] William Heineman n, London, 1928.

representations have been made to the University of London, urging the authorities to institute a post-graduate course of psychiatric training for social workers; courses have been held by the Association, and workers have been trained at the central office. A special course was held in May for medical men and women; 28 of the 45 who attended were school medical officers. Another course was held for magistrates and was greatly appreciated. The courses for teachers are well established and over 1,000 teachers have now been through them, but there is still an inadequate supply of suitable workers for special classes of dull and backward children. A variant of the teachers' course was held at the request of the Board of Control for inquiry officers and supervisors of occupation centres. There are now 109 occupation centres in England and Wales, most of them under the direct management of their local associations. Four new centres were opened during the year under review—a feat which involves a great deal more work than most people would imagine. Before a centre can be opened numbers of children have to be visited, those suitable for the centre have to be selected, parents' consent has to be obtained, premises found, committee formed, grants obtained, staff trained and appointed, and arrangements for transport made. The guardianship scheme is, in the absence of institutional accommodation, the most fruitful method of dealing with defectives. The C.A.M.W. has now made its scheme self-supporting and so extensive that an assistant officer has become necessary. The work at the office shows no sign of diminishing, but it is interesting to learn that far more "better-class" parents now apply for advice. It is no easy task to find a suitable institution for a defective, even for families who can afford to pay, but the Central Association has all the information docketed, and can often direct guardians to the most suitable colony or home. A register of nurses and governesses is also kept, but here, again, the demand greatly exceeds the supply. Certain trades employ large numbers of defectives, and the association is naturally anxious to have access to their records. Up to date three of the principal trade-boards have agreed to give information and four others are willing to supply figures without names. A hopeful offshoot of the Association is the Child Guidance Council, now a separate organisation with its own Council, offices, and staff. As is well known, the Commonwealth Fund of America is coöperating with this Council, and a Child Guidance Clinic is to be opened in London shortly. Five of the C.A.M.W. social workers have had a year's special training at the New York School of Social Service at the expense of the Commonwealth Fund, and the Secretary, Miss Evelyn Fox, has paid a three months' visit to various centres of work in America.

ICTERUS NEONATORUM.

THE origin of the so-called physiological jaundice of the newly born presents a problem which is still to a large extent unsolved, while a constant succession of theories has kept alive the interest which has been taken in it by the physiologist and the physician. Since the days of Morgagni, who attributed it to plugging of the bile-duct by milk curds—a view amended by Virchow to a similar action of mucous plugs—a series of explanations have been propounded of which few have stood the test of time. In recent years explanations which refer the origin of the jaundice to the alimentary tract have receded from favour, the field being occupied by two principal theories—namely, hæmatogenous and hepatogenous origin. The balance of opinion, at any rate in this country, has favoured the former view, in some degree as a result of the confirmation given to it by the Van den Bergh reaction. Nevertheless the hepatogenous view, in favour of which A. Yllpö has adduced much cogent reasoning, has not been without its supporters. Prof. P. Lereboullet,[1] who has long been a contributor to the literature of the subject, suggests in an interesting review that the hæmatogenous and hepatogenous theories are by no means as mutually exclusive as has been represented by their respective exponents. From the clinical aspect Prof. Lereboullet reminds the reader of three important facts: (1) that the icterus is preceded by an erythrodermic phase; (2) that the fæces are not decolorised; and (3) that the jaundice is in most cases acholuric. Its occurrence is especially frequent in twins, and in infants born prematurely or after difficult labour. The most important fact established by experiment is that the blood of the infant at the moment of birth contains bile; there is a physiological bilirubinæmia independent of the subsequent development of jaundice. It is also found that the blood of the cord contains less bile than that of the fœtus, and the maternal blood contains three times less bile than the blood of the cord. Hence it may be inferred that the blood returning from the placenta loses some of its bile-pigments in the maternal circulation, and that from the point of view of the fœtus the cord represents the main path of excretion of bile-pigments, only a portion passing into the meconium. It is undoubtedly true that a tendency to hæmolysis is present in the first few days of life; that is seen in the erythrodermic phase which so often precedes jaundice and which may be attributed to hæmoglobinæmia. These two factors, hyper-hæmolysis and hyper-cholæmia, are therefore present in *normal* infants after birth. At birth the ligature of the cord puts an abrupt termination to the path of excretion of the greater part of the fœtal bile. As a result of this, the bile content of the blood rises, just at the moment when the existing number of the red corpuscles is becoming in excess of the infant's requirements. The kidneys have not as yet acquired the faculty of excreting bile, as is shown by the acholuric type of jaundice. The liver is in process of acquiring this faculty, but jaundice will occur in infants in whom it is not acquired with sufficient rapidity to keep pace with the hypercholæmia occasioned by ligature of the cord and accentuated by hæmolysis.

DUST AND TUBERCLE.

THE evil effects on the respiratory system of the inhalation of various forms of dust have been recognised for many years. Clinical and pathological investigations have shown that while some dusts are relatively innocuous, others, notably the hard silica dusts, produce profound changes in the lungs and influence very definitely the development of certain infections, especially tuberculosis. This much is generally accepted, but the exact method by which the pulmonary changes are brought about is not yet settled. And there is still less agreement as to the way in which the silica helps in the progress of the tuberculous process. The matter has been subjected to experimental investigation by many workers but with inconclusive results. It is easy enough to show that silica has a deleterious action on the tissues of the body, which, if continued, is followed by extreme fibrosis; and it can also be demonstrated in laboratory animals that the presence of silica increases the pathogenicity of the tubercle bacillus. But the production of the pulmonary lesions with which we are familiar in stone-masons and quartz-miners has yet to be achieved. The difficulty probably lies in the choice of the experimental animal. Rabbits and guinea-pigs can be exposed to dust atmospheres containing a vastly greater concentration of silica than any to which an industrial worker would ever be subjected, but they do not develop the characteristic pulmonary lesions. Such an experiment has been described in the *American Review of Tuberculosis* by H. S. Willis.[2] Guinea-pigs were exposed to a concentrated atmosphere of silica in a dusting chamber for periods ranging from 24 to 37 months. The exposures lasted for about three hours each day, for four or five

[2] Amer. Rev. Tuberc., 1928, xvii., 253.

days a week, the animals being in the chamber for roughly 50 hours a month. Even after three years of this treatment the animals showed surprisingly few pulmonary lesions. Moreover, subcutaneous inoculation with tubercle bacilli was not followed by more rapid or extensive tuberculosis in these animals than in controls. Negative observations of the kind are familiar to workers in this field. It may be that the upper respiratory tract of animals which normally carry their noses so close to the earth are so constructed that the air reaching the pulmonary alveoli is efficiently filtered. Or it may be that the respiration of animals quiescent in the dusting chamber is abnormally shallow. Whatever the reason, it is clear that the experimental conditions do not represent those occurring in the dust industries. Negative results must not be regarded as disproving our present conceptions of the pathology of miners' phthisis, for the positive evidence available is far too abundant to be upset by what are clearly imperfect experiments. On the other hand, the prevention of pneumokoniosis in dangerous industries has steadily progressed in recent years. In a report [3] recently published by the Miners' Phthisis Medical Bureau of South Africa the measures taken for the detection and prevention of this disease are recorded in detail, and in an address [4] delivered by Dr. L. G. Irvine, chairman of the Bureau, the matter is discussed in more general terms. The work of the Bureau is well known, and we are glad to hear from Dr. Irvine that the present position is more satisfactory than for many years. Improved methods of diagnosis have resulted in the detection of many cases of silicosis in the earliest stages, which formerly would not have been recognised, and thus the apparent incidence of the disease has increased. In spite of this the latest recorded figures show less silicosis among the Rand miners than was to be expected from the experience of previous years. Silicosis and tuberculosis run closely together; the dust factor in the Rand mines has already been dealt with very effectively, and unceasing care is exercised to see that the atmospheric conditions underground are as good as they can possibly be. The control of tuberculosis underground, which practically means the detection of the "carrier," is also receiving the most careful attention, and it is not unreasonable to hope that the incidence of miners' phthisis will diminish still more in the future.

PRESCRIPTIONS FOR NASAL CATARRH.

DURING the recent wave of infectious colds over the American continent it is reported that persons who performed a nasal toilette in public were looked at askance and that a sneeze was tantamount to exclusion from a theatre. Nasal catarrh, however, is not an ailment for which many effective remedies have been discovered, and certainly very few are universally recognised. An Italian proverb states that a cold when left alone runs for 21 days and, when treated, for three weeks. Nevertheless there are certain procedures which, if applied early, can shorten matters. It is agreed that a cold may sometimes be nipped in the bud by a good sweat, induced by a cabinet, a hot bath, or a pile of blankets, assisted by an antipyretic. Prof. H. Beyer, who has given prolonged study to the prevention and treatment of *Schnupfen* in Berlin, has recently set out his experience [5] in a form which may be of use to others at the present time. At the outset, while there is still hope of aborting the cold, he recommends: calc. lact. 4·0, dionin 0·4, made up to 100·0 with half-and-half raspberry syrup and water, the whole amount to be taken in the course of the day. Mild anæsthetic sprays and the insertion in each nostril for an hour or two of a plug of cotton-wool steeped in 20 per cent. ichthyol solution, may also avert the attack. Prof. Beyer also mentio Brüning's local light bath, which is applied to the fa while the patient, in a recumbent position, breath through a glass tube. It raises the local temperatu to about boiling-point without serious inconvenienc and avoids the disadvantages of a general applicatio of heat. If these methods are unsuccessful, the patie should, he says, remain in bed, the swelling ar secretion of the nasal area being treated wit inhalants such as lysoform, or acid. carbol. liq liq. alum. acet., of each 5·0, in 15·0 of rectifie spirit and 10·0 of distilled water. Ten drops a placed on a piece of wadding and inhaled. Cocaine i minute doses affords relief, and the danger of misha is negligible. A good nasal snuff is given as: co mur., menthol, of each 0·1 in 10·0 of milk suga and some firms market a composition of cocaine wit menthol and adrenalin. Menthol, in a 0·2 per cen solution with liquid paraffin, is said to be good, bu must never be given to infants. In children th condition should be regarded with still more respec as the obstruction may lead to suffocation, convulsion or the inhaling of the tongue, and the infection itse may be serious in a weakly or predisposed child Rubbing with wool soaked in equal parts of spirit an glycerine, and moistening the air with the steam o boiling water containing some menthol crystals ar both useful measures. Fever should be treated wit 1·5 of pyramidon once or twice a day, or in childre over six months with half a tablet of aspirin. T mitigate breathlessness in sucklings at feeding tim due to nasal swelling, a mixture of adrenalin 1–100 one part, borated water two parts, may be droppe into the nose. Nose-bleeding during a cold in infant sometimes points to diphtheria or syphilis. Diphtheri carriers often suffer from an outbreak of their specifi fever disguised as catarrh, in which purulent epistaxi replaces membrane building; loss of appetite alimentary troubles, and dyspnœa from membran soon betray the condition. The local applicatio recommended is one also used as a routine prophylaxi for carriers—namely: protargol 3·0 dissolved i 5·0 of cold water and incorporated in lanolin 10·0 vaselin. flav. 30·0. The dangerous gangrenous form of nasal diphtheria is not common, but should b borne in mind as a reason for assiduous local treat ment. Syphilitic colds break out a fortnight befor the rash and differ from ordinary catarrh in a much more pronounced swelling of the nasal mucosa, which secretes large quantities of reddish-brown pus, which may flow down the nose and stain the face. When the ordinary treatment of catarrh fails it is worth while trying an ointment made up as follows: hydrarg præcipit. alb. 0·2, lanolin 3·0, paraff. liq. 2·0. This should be applied to the nostrils once a day with a spatula. For sinus infection Dr. Beyer recommends the local light bath, along with a mixture containing pot. iod., sod. iod. of each 5·0 in aq. distill. 20·0 of this 5–10 drops are taken in milk three times a day Saline douches, assisted by laxative mineral water to avoid hyperæmia of the mucosa, should be used in all catarrh; glycerine tampons left in place for half an hour and hydrogen peroxide douches will relieve the thick secretion and fœtor which follow ozæna, after which tampons soaked in eucupin 2·0 with aq. distill 40·0 and lanol. ad. 100·0 are applied. Practitioners may find useful some of these prescriptions, which are throughout transcribed in metric form.

THE ARMY MEDICAL SERVICES.

SOME confusion has arisen following the announcement, in our issue of Dec. 15th, 1928 (p. 1262), concerning an Advisory Board and a Consultative Committee in connexion with the Army Medical Services. The establishment of an Army Medical Directorate Consultative Committee is quite independent of the reconstitution of the Army Medical Advisory Board It will be remembered that after the war the members of the Board, at that time Lord Dawson, Sir Berkeley Moynihan, Sir Robert Jones, Sir Harold Stiles, Sir William Horrocks, and

[3] Union of South Africa: Report upon the work of the Miners' Phthisis Medical Bureau for the year ended July 31st, 1927. Pretoria: Government Printing and Stationery Office. 1928. Pp. 61. 5*s*. 6*d*.

[4] Present Position of Miners' Phthisis on the Rand. An address to the Association of Mine Managers. By L. G. Irvine, M.D., B.Sc. (Obtainable from the Bureau.)

[5] Deut. Med. Wochens., 1928, liv., 512.

the President of the Medical Board at the India Office (ex officio for Indian affairs), ceased to be paid but continued to give voluntary service. The Board met seldom during the succeeding years except to advise the Secretary of State on the appointment of Director-General, and in 1928 Sir Robert Jones and Sir Harold Stiles retired from its deliberations. It was then recognised that the terms of reference of the Board required amendment and that men in civilian consulting practice were unable to give up the time necessary to carry out all the duties which then devolved upon the Board. At the same time many other questions, such as the lack of candidates for the Royal Army Medical Corps, post-graduate instruction, and the future prospects of the Corps, were presenting themselves on which the Director-General wanted the constant advice and help of the civil profession. For these reasons it seemed desirable to establish a board or committee covering a wider sphere of the civil profession and with more members, so that the Director-General could have more frequent meetings with at any rate a proportion of the members. The Secretary of State therefore decided to retain the Army Medical Advisory Board of four civilian members to advise him on matters of policy vis-à-vis the civil profession, and to constitute a new committee to be called the Army Medical Directorate Consultative Committee, with the Director-General as chairman, to discuss matters of departmental rather than general interest. The members of this committee were chosen to cover as wide a field as possible and in particular to secure liaison with the medical schools. As we have already stated, they consist of Major-General H. B. Fawcus (vice-chairman), Prof. J. Barcroft, Lieut.-Colonel Sir Robert A. Bolam, Colonel Sir E. Farquhar Buzzard, Colonel T. R. Elliott, Captain J. Fraser, Colonel G. E. Gask, and Colonel A. E. Webb-Johnson, with Major C. M. Drew as secretary. Hygiene, pathology, and radiology are not represented on this Committee since there already exist strong advisory committees on these subjects. One of the most pressing needs of the Medical Services of the Army is an adequate supply of candidates and this will be one of the first matters to be discussed by the Committee. It is expected that visits will be paid to the military hospitals by members and that much valuable advice will be obtained. It is clear that the Board and the Committee are quite distinct from each other and have no interdependence. The Board acts in an advisory capacity to the Secretary of State, and the Committee to the Director-General of Army Medical Services and through him to the Adjutant-General and the Army Council.

DRUGS FOR INSURED PERSONS.

THE memorandum recently issued by the Medical Practitioners' Union seems to be founded on a misconception of the arrangement made between the Ministry of Health and the Retail Pharmacists' Union. For some time past in most if not all of the insurance areas analysis has shown that the cost of the actual drugs is less than the amount paid to the chemists for dispensing them. Now the sum of money allocated to the drug fund as part of medical benefit is a fixed quantity, and the arrangement with the chemists implies that in accepting the whole of this sum they are taking the risk of a loss or a surplus according to the amount required for the supply of medicine to the insured population for any year. As far as the year 1928 is concerned the chemists will probably receive the whole of the cost of the drugs plus their dispensing fees to within a small percentage of the full amount. To put it in a sentence, the chemists' bills are discounted on the payment for services rendered, but are paid in full as far as the cost of the drugs is concerned. It seems therefore hardly fair for the Union to say that the control of the drug fund has been "handed over by the Minister of Health to the Retail Pharmacists' Union," and the statement that "the amount of medicine for the insured is strictly conditioned by what is left over after a working profit is provided for the pharmacist" does not represent the facts of the case. The amount of medicine is conditioned solely by the clause in the Act of Parliament which guarantees proper and sufficient medicine for adequate treatment. What is proper and what is sufficient is determined and can only be determined by insurance practitioners themselves. Even in a case investigated under the regulations for alleged excessive prescribing the determination and decision are in the hands of the practitioner's colleagues on the local panel committee. It may be remarked that the attempt at restriction made by the London Insurance Committee recently has apparently been given up. The report of the last meeting of the London Panel Committee indicates a determination to leave the ordering of any remedy to the absolute discretion of the practitioners themselves. We commend the Union for its jealous watch over the interests of medical practice; in this matter, however, there seems no ground for anxiety.

ŒDEMA IN EXOPHTHALMIC GOITRE.

As long ago as 1897 Hector Mackenzie pointed out [1] that œdema may appear in several phases of Graves's disease. The illness may be heralded by a slight general œdema; during the course of the malady a very persistent local œdema may affect the eyelids; sometimes a curious swelling is met with in the lower extremities, resembling the swelling of myxœdema in being firm, non-pitting, and yielding no fluid on acupuncture; very occasionally puffy urticarial lesions are seen at the onset of severe cases. A solid infiltrated type of œdema is described as not uncommon in most English text-books. Œdema of cardiac origin is of course well known. A complete and erudite account of the whole subject has lately appeared [2] from the pen of Dr. Malte Ljungdahl, of Malmö, Sweden. The writer reviews the literature back to Mackenzie's article, mentioning Maude's original classification into Œdema of cardiac origin, Œdema of "nervous" origin (which would now be called "vasomotor"), and Patchy and fugitive types. He describes fully and clearly six cases of his own showing well-marked œdema and bases on these three types of œdema—namely: (*a*) œdema dependent on stasis and cardiac failure, especially failure of adequate diastolic filling; (*b*) œdema in circumscribed zones as described by Quincke; and (*c*) a firm, non-pitting œdematous infiltration of the skin in certain sites, notably the eyelids and the legs. The exact causation of the œdema under the two latter rubrics is not clear, but Dr. Ljungdahl suggests that it is part of the toxæmia of which hyperthyroidism is itself a manifestation. This view is supported by the fact that the lesions in type (*b*) may be indistinguishable from those of erythema multiforme. All three types of œdema may be prolonged, considerable and relapsing without prejudice to the prognosis—a fact on which the author lays much stress. Along with the œdema may appear icterus, scleroderma, or pigmentation as allied phenomena. In regard to treatment, Dr. Ljungdahl regards iodine as specific for all such œdematous states, and his charts illustrative of the diuretic effects of this drug are very striking. Three drops daily of Lugol's solution rapidly increased to 18 or more drops will resolve the œdema besides bringing about a general amelioration in the symptoms and a lowering of the metabolic rate. If icterus is present it also will yield to iodine. The value of iodine in Graves's disease has long been known; although its mode of action is still unsettled, it is frequently given as a preliminary to thyroidectomy. American experience was recently reviewed in these pages.[3] Dr. Ljungdahl's work is a welcome addition to our knowledge.

COUNTY HOSPITALS IN THE IRISH FREE STATE.

AT the meeting of the Council of the Irish Medical Association held last week attention was given to the present condition of many of the county hospitals, and the following resolution was passed :—

"The Council of the Irish Medical Association has had under consideration the unsatisfactory conditions under which the surgeons of many county hospitals are expected to do surgical work. In many cases there has been no structural alteration for generations, and in few is there adequate equipment. At the same time surgeons are pressed to undertake major surgery which cannot be done with due regard to the welfare of patients. The condition is such as to demand immediate attention."

When the public medical services of Ireland began to undergo reform some seven or eight years ago, it was an essential part of the scheme that there should be in each county a county hospital capable of dealing with the ordinary surgical work of the county. With this end in view, as vacancies occurred in the position of county hospital surgeon, superior surgical qualifications were demanded from those who sought appointment. It was assumed that the hospitals would be so equipped that surgical work should be done in accordance with modern requirements. In 1924, in its memorandum of evidence submitted to the Committees of Inquiry on National Health Insurance and the Medical Services, the Department of Local Government and Public Health stated that the necessary development had taken place, and that the hospitals were provided with the scientific equipment essential to the performance of their duties. Verbal evidence submitted later by the Department's officials failed to substantiate this claim, and even at the present day comparatively few of the county hospitals are equipped in such a way as to justify the performance of major surgical operations. At the same time the surgeons are criticised by their boards of health if they think fit to refer patients for major operations to the city hospitals. The surgeons have also another, and a more personal, grievance. Many of them, writes our Dublin correspondent, were appointed with a definite promise that provision would be made in the hospitals for the accommodation of private patients, who, in addition to paying for their accommodation, would pay fees to the surgeons. This promise affected the salaries accepted by the newly appointed surgeons. In few cases, however, has the promise been fulfilled and regulations adopted to govern the admission of private patients. The net result is that the health authorities, failing to fulfil the promise made, have obtained the surgeons at lower salaries than would have been accepted had the promise not been made.

THE VIRULENCE OF THE BLOOD IN TUBERCULOSIS.

AN interesting investigation into the virulence of the blood of tuberculous subjects has been performed on a large scale by Dr. R. Pla y Armengol.[1] He has confirmed by numerous experiments his discovery that blood taken from a guinea-pig 24 hours and onwards after the animal has been injected with caseous material or with tubercle bacilli is uniformly fatal to healthy guinea-pigs. Some die in a week, others after two or three months. Only in a very small percentage of cases do the guinea-pigs develop typical tuberculosis. In the rest no tubercles develop and no Koch's bacilli are found, but the animals show a progressive wasting. Details of autopsies are not supplied, but it is stated that the lymph glands are usually normal. The blood of 27 patients in whose sputum tubercle bacilli had been demonstrated was also regularly fatal to guinea-pigs. When the batch of animals into which this human blood was injected were just dead or dying, 2 c.cm. of blood from each of them was injected subcutaneously into other guinea-pigs, with uniformly fatal results. This passage was repeated three times in each case. Among the whole series of guinea-pigs, of which 675 were used in all, the injection was fatal in all but nine.

Dr. Armengol suggests that the experiments prove the constant presence in the blood of tuberculous animals of a living organism which is able to multiply in the body, and he believes this to be the tubercle bacillus in another form. This argument really turns on the fact that he failed to find Koch's bacilli or the usual lesions in the majority of the animals. It is admittedly sometimes a laborious task to demonstrate tubercle bacilli in lesions which are known to be tuberculous; there is rarely, however, any difficulty if the animal dies of the disease. Similar observations to those of Dr. Armengol have been made before, but the usual explanation given has been that of intercurrent or secondary infection. This Dr. Armengol rejects because of the regularity with which a fatal result occurs. The objection is reasonable, but his article would have had more value if he had supplied more information about control experiments. It is possible that we are dealing here with the filterable form of the tubercle bacillus (Fontes) whose existence has been supported by the work of Vaudremer, Valtis, Calmette, and others.

[1] Publicaciones del Instituto Ravetlat-Pla, Barcelona, October, 1928.

AT a meeting of representative dermatologists from Leeds, Liverpool, Manchester, and Sheffield held in Manchester on Jan. 15th, it was decided to expand the Manchester Dermatological Society into a North of England Dermatological Society. The Society, in addition to the annual general meeting, will hold four clinical meetings each year—one in Liverpool, one in Sheffield, and two in Manchester. The following officers were elected :—President: Dr. L. Savatard (Manchester); Vice-presidents: Dr. R. W. McKenna (Liverpool) and Dr. A. R. Hallam (Sheffield); Secretary: Dr. P. B. Mumford (Manchester); Members of Council: Dr. J. T. Ingram (Leeds), Dr. W. Dyson (Manchester), and Dr. G. H. Lancashire (Manchester). Any dermatologists, other than those already notified, in the North of England who would like to join, are asked to write to the Secretary, Dr. Mumford, 96, Mosley-street, Manchester.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments have been made:—Surg. Rear-Admirals: A. J. Hewitt to *Pembroke*, and H. C. Whiteside to *Victory*, for R.N. Hospital, Haslar; Surg. Lt. J. W. Nesbitt to *Pembroke*.

ROYAL ARMY MEDICAL CORPS.

Capts. to be Majs.: J. P. Macnamara, J. W. Hyatt (Prov.) and remains secd., T. Stanton, and T. Parr (Prov.) and remains secd.

Lt. (on prob.) J. C. Gilroy, from the secd. list, is restd. to the estabt.

ARMY DENTAL CORPS.

The undermentioned Lts. (on prob.) are confirmed in their rank: H. L. Foulkes-Roberts, T. R. Wall, J. A. O'Connor, and H. S. Golding.

ARMY RESERVE OF OFFICERS.

Lt.-Col. G. B. Crisp, having attained the age-limit of liability to recall, ceases to belong to the Res. of Off.

ROYAL AIR FORCE.

Flying Officers J. E. Foran and M. O'Regan are promoted to the rank of Flight Lt.

RESERVE OF AIR FORCE OFFICERS.

Flying Officer W. B. Stott relinquishes his commission on completion of service.

INDIAN MEDICAL SERVICE.

Lt.-Col. R. W. Anthony to be Maj.-Gen.
Capt. G. A. Hildreth to be Maj.
Lt.-Col. J. B. Christian retires.
Temp. Lt. Prag Nath Kapur relinquishes his temp. commn.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

XIX.

THE INTERPRETATION OF BLOOD-SUGAR ESTIMATIONS.

THE presence of an adequate amount of sugar in ne blood is essential for life and its many activities. lthough the blood-sugar increases after a carbo- ydrate meal no sugar is excreted in the urine of ost healthy people. The presence, therefore, of a educing substance in the urine which has been proved be dextrose should always arouse suspicion and n estimation of the blood-sugar should be made. Whether a glucose-tolerance test need be performed epends on the amount of sugar in the blood, as will e seen below.

Collection of Blood.

The time at which the blood should be collected is ery important. If the examination is being made for he purpose of establishing a diagnosis when sugar has een found in the urine, the blood should be collected ne to two hours after a meal at which at least 2 oz. of read have been eaten. This is essential in the mild ases, since the blood-sugar may only be raised for a hort time, and a wrong diagnosis has been made by ollecting the blood some hours after the meal or after period of strict dieting. If the case is a severe one, he blood-sugar will probably be raised throughout the ay and the blood can therefore be collected at any ime.

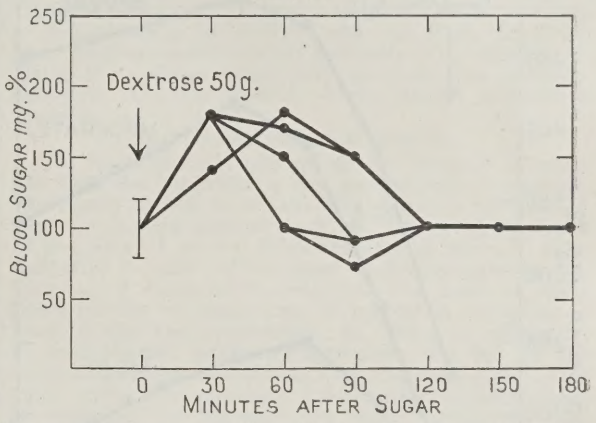
If the patient is having insulin, the blood must also e collected at a definite time. It should be collected 1) before the morning dose of insulin if it is desired to now whether the blood-sugar has been brought down o normal at the beginning of the day. If it is nconvenient to see the patient before breakfast, a arbohydrate-free meal should be eaten and the blood ollected as soon as possible after it, and the insulin nd usual carbohydrate given later. (2) The blood hould be collected three to six hours after the insulin o as to make certain that the response to the insulin s the correct one. (3) It may be necessary to collect he blood again immediately before the evening ose of insulin. The information obtained at hese three times gives the best indication of the eaction of the patient to insulin, though it must e admitted that it is possible to gauge the correct ose of insulin with very few blood-sugar estima- ions. After the dose of insulin and the diet ave been stabilised, one of these times should be hosen, the blood for testing should be collected lways at this time, so that the progress of the case an be assessed. If a gain or loss of sugar tolerance as occurred, it is sometimes of assistance to estimate lood-sugar at all three times in order to adjust the ose of insulin.

Collection of Blood.—The blood can either be ollected from a vein by means of a sharp needle and yringe or from the capillaries of the ear-lobe or nger. If the finger is used, it is important to place he hand in hot water, so as to make certain that the kin is hot and contains plenty of blood. The best eedle to use is the "blood gun" recommended by rof. Herrmann Sahli. After the prick has been ade a piece of fine rubber tubing should be wound ound the base of the finger in order to make the lood flow more freely. If the blood has to be ent by post to the laboratory, 2 to 5 c.cm. should e collected from a vein. In order to prevent he clotting of the blood and the disappearance f the sugar, a mixture of potassium oxalate 4 parts nd potassium fluoride 1 part must be added. For 5 c.cm. of blood, 0·02 g. of the mixture is sufficient; and this can be roughly measured on the point of a large pocket knife. The blood should be placed in a tube or bottle and then in a small tin to prevent any risk of breakage.

Normal Values.

To interpret the result of a blood-sugar estimation correctly the normal variations in the amount of sugar in the blood must be understood both in health and disease (see Fig. 1). When a healthy person has had no food for three or more hours the sugar in the blood varies from 80 to 120 mg. (0·08 to 0·12 g.) per 100 c.cm. [It is better to express the result in milligrammes—e.g., 95 per 100 c.cm. instead of as a decimal part of a gramme—e.g., 0·095 per 100 c.cm., because it is much easier to use a whole

FIG. 1.



Normal variations for capillary blood. (For venous blood the readings are 20–30 mg. lower.)

number and less likely to cause mistakes.] After a dose of 50 g. of dextrose taken by the mouth, or after a heavy carbohydrate meal, the blood-sugar increases rapidly, and may have begun to rise after 10 mins.; it usually reaches a maximum after 30 mins., and may have returned to the fasting value after 60 mins. The usually accepted maximum for capillary blood of a normal person after 50 g. of dextrose is 180 mg. per cent., but it may be only 150 mg. or even less. The maximum figure may not be reached until after 60 mins., and the return to the fasting value may not take place until after two to three hours. The actual figures depend on whether the blood comes from the capillaries or veins. The capillary blood is identical with that obtained from an artery. When the patient is fasting the two estimation are identical, but after the dose of sugar the capillary blood is usually 20 mg. higher than the venous blood. Only the figures for the capillary blood will be considered in this article.

The Lag Curve.—A rare occurrence is a rise in the blood-sugar to 230 mg. after 30 minutes. Provided that the blood-sugar has fallen below 180 mg. after 60 minutes and below 130 mg. in 120 minutes, the sugar tolerance is regarded as normal, though it is advisable to repeat the test three months later.

Abnormal Values.

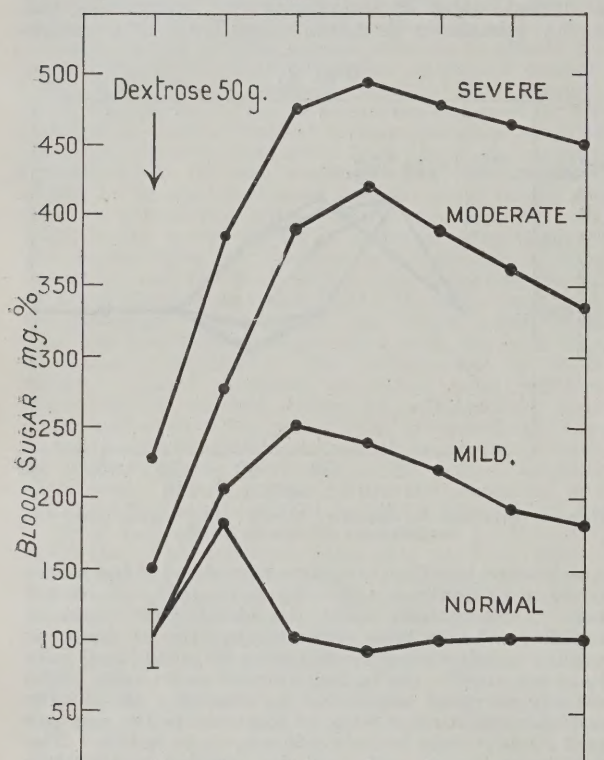
If a patient has a mild form (Fig. 2) of diabetes, the fasting value of the blood-sugar is often normal —i.e., below 130 mg. per cent.—but 30 mins. after 50 g. of dextrose it has usually risen above 200 mg. per cent. After 60 mins. it is usually still higher, and does not return to normal until more than three hours have elapsed. In a more severe case, the fasting value is often raised to 150 or 180 mg. per cent. and the blood-sugar may rise to more than 250 or 300 mg. per cent. after 30 mins. and over 400 mg. per cent. after 60 mins., and may not return to normal for several hours. If the initial value is over 200 mg. per cent. the blood-sugar may rise to more

than 500 mg. after 60 mins. A sugar-tolerance test should never have been asked for if the initial blood-sugar was over 200 mg. per cent., since this alone would show that the patient had a low sugar tolerance.

If an isolated determination of the blood-sugar is made, it is essential to know the nature and time of the last meal and whether the blood was collected from the capillaries or a vein.

If the blood-sugar is over 200 mg. per cent. 60 mins. after the last meal it is certain that the patient has a low sugar tolerance. If it is 180 mg. per cent.

FIG. 2.



one hour after a meal in which carbohydrates have been eaten, it is only suspicious, but if it stands at this figure two hours after the meal, the patient probably has a low sugar tolerance; but in order to prove it definitely the tolerance must be tested with a 50 g. dose of dextrose. If, however, the blood-sugar is 180 mg. per cent. three hours after a meal, the patient certainly has a low sugar tolerance.

It should be remembered that although the blood-sugar of a normal individual is not raised above 180 mg. per cent. after meals, it is sometimes raised above 200 mg. in moments of excitement and nervous strain when glycosuria may occur. It is also sometimes altered in certain diseases. Thus a severe carbuncle or numerous boils may cause a rise in the blood-sugar and sugar may even appear in the urine, although the sugar tolerance, both before and after the illness, is apparently quite normal. Such an observation should, however, raise the suspicion that the sugar tolerance is rather lower than that of most individuals. When the patient has a definitely lowered sugar tolerance, especially if it is sufficiently low to need insulin to keep the blood-sugar within normal limits, any infection may cause a rise in the blood-sugar and the presence of sugar in the urine. A severe infection may precipitate the onset of coma. Diseases of the thyroid gland, like exophthalmic goitre and myxœdema, may cause a lowering of the sugar tolerance, and in these conditions the sugar-tolerance curve may show a rise above 200 mg. after 30 mins. and the return below 200 mg. may be delayed for two or more hours. The blood-sugar of a healthy person may be lowered in extreme exhaustion—e.g., during a Marathon race or after an excitement is over. Moderate exercise may cause hypoglycæmia in patients who are having insulin, and it is more likely to occur three to six hours after the injection of insulin. They should be warned of this complication.

Relation of Glycosuria to Glycæmia.

Sugar is not detected in the urine by the ordinary tests unless the blood-sugar rises above 180 mg. per cent. This level is termed the threshold of the kidney. It may be raised or lowered. If it is raised, sugar may not appear in the urine even though the blood contains 250 or 300 mg. per cent. of sugar. The correct diagnosis can only be made by means of an estimation of the blood-sugar.

If the threshold is lowered the patient passes sugar in the urine although the blood-sugar lies within the normal limits. If it is only slightly lowered, say to 150 mg. per cent., sugar will appear in the urine after a carbohydrate meal, and suggest that the patient has a mild form of diabetes. If the threshold is below 100 mg. per cent. sugar will be present in the urine throughout the day, and will suggest that the patient has a severe form of diabetes. The diagnosis is suggested by the absence of the usual symptoms of thirst and polyuria, but can only be made with certainty by means of a sugar-tolerance test after 50 g. of dextrose.

GEORGE GRAHAM, M.D. Camb., F.R.C.P. Lond.,
Assistant Physician, St. Bartholomew's Hospital.

DONATIONS AND BEQUESTS.—Mr. James Mills Travis, Springhead, Saddleworth, Yorks, left £1000 to the Oldham Royal Infirmary for a bed.—Miners and other workmen in the Wigan district contributed £16,515 last year to Wigan Infirmary in voluntary weekly levies.—Mr. John Davison Bland, J.P., of Kippax Park, Yorks, and Torquay, left, besides other bequests, £4000 to the Leeds General Infirmary, £2000 to the Leeds Public Dispensary, £1000 each to the Leeds Women's and Children's Hospital, Leeds Maternity Hospital, St. Anne's Home, Bridlington, and the Queen's Hospital for Children, Hackney, London.—Miss Henrietta Fell, of Westbourne-grove, Scarborough, besides other bequests, left £1000 to Scarborough Hospital and the residue of her property, about £30,000, to the Birkenhead Hospital.—Mr. Isaac Dymmock, of Redland, Bristol, left £1500 to Bristol Royal Infirmary to endow a bed to be called the "Isaac Dymmock bed."—Mr. and Mrs. Joseph Smith, of Holmfield-road, Leicester, have given £500 to the Leicester Royal Infirmary for the endowment of a bed to mark the celebration of their golden wedding.—Mr. John O'Connor, K.C., of Frognal-mansions, Hampstead, London, N.W., besides other bequests, left £2000 to the Cancer Hospital, Fulham, "in grateful remembrance of services once rendered to a dear relation."—Mr. Joseph Batty, Whitchurch, left £1000 to the Cardiff Infirmary and to King Edward VII. Memorial.—Mr. Charles Stones Gray, of Rozel, Ryde, retired dental surgeon, left £1000 to St. Dunstan's Hostel, £300 to George Muller's Orphanage, Bristol, and £200 to Dr. Barnardo's Homes.—Mr. Walter Samuel Baines, Folkestone, Kent, on the decease of his wife, left £5000 to the Sutton (Surrey) Hospital, and after further bequests the balance to Dr. Barnardo's Homes, whom failing to King Edward's Hospital Fund.—Mr. Arthur Henry Foster, Green-lane, Moseley, Birmingham, solicitor, amongst other bequests, left £1000 each to the Birmingham General Hospital, the Queen's Hospital, Birmingham, the Birmingham and the Midland Homœopathic Hospital; £200 each to the Birmingham and Midland Ear and Throat Hospital, the Birmingham Royal Institution for the Blind, and the Birmingham General Dispensary; and a sum sufficient to endow a bed or cot to the Children's Hospital, Birmingham.—Subject to certain annuities, Mr. Haywood Smith, of Penwellyn, Sidcup, who left £47,259, bequeathed the whole of his estate to the Sidcup Cottage Hospital and the Chislehurst, Orpington, and Cray Valley Hospital.—Mr. Charles Courtenay Cowlin, of Somerset, left, among other bequests, £1000 to the Bristol General Hospital.

Special Articles.

THE STUDY OF INDUSTRIAL HYGIENE.

By M. GREENWOOD, D.Sc., F.R.S., F.R.C.P. Lond.,

PROFESSOR OF EPIDEMIOLOGY AND VITAL STATISTICS IN THE UNIVERSITY OF LONDON (LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE).

EVERYONE knows that, since the war, the study of industrial hygiene and medicine has entered upon a new phase. Before 1918 research was largely a by-product of the official duties of civil servants or done in the leisure of busy physicians and surgeons; since 1918, not only have many trained investigators specialised in industrial-medical research, but the appointment of whole-time medical officers by employers of labour is no longer very exceptional. Contemporaneously with this increase of skilled observers—in part, of course, its cause—has been a growth of demand for information from all classes; various national and international organisations seek to supply this demand and, as will appear later, the quality of the supply varies. Comparing what we have learned in the last ten years with what was known before, anybody not familiar with the history of scientific progress is likely to be disappointed. He *must* feel this, if his criterion be the number of practically important discoveries made, for these have been few and unspectacular.

Those really familiar with the methods of science will not, however, be discouraged. They will be satisfied if it can be shown that the *methods* of research now coming into use are more powerful than those of a generation ago and will not expect a few years' use of even powerful new methods to yield results more valuable than that which the patient observation of such men—to cite only our countrymen—as Thackrah, Greenhow, Whitelegge, Oliver, Legge, and Collis has furnished in a century. The work of the last ten years has been primarily important in methodology and—as *always* happens when we enter upon a fruitful line of research—we have learned that apparently unrelated problems, each seemingly capable of solution by an ad hoc method, are really interrelated. Serious investigators have become more conscious of their own ignorance and less willing to lay down general laws. The history of almost any of the researches of the Industrial Fatigue Research Board illustrates this. I choose, as an example, one in which I have had a small personal share—viz., the study of the ætiology and prevention of industrial accidents. The long and, on the whole, creditable history of measures taken to reduce the risk to life and limb in factories in this country is well known. It is equally well known that of the accidents now occurring only a small proportion could be prevented by action beyond the control of the worker. It has been authoritatively stated that "however well machinery is guarded we cannot look for more than 10 per cent. reduction in the accident rate by the provision of safeguards alone."[1] In other words, the greatest proportion of industrial accidents is due to factors other than those which can be eliminated by administrative or mechanical betterment.

This leads us to look at the problem from another angle. Let us suppose that we have a record of this kind: A number of people all doing the same work under the same environment have been observed for the same time, and we are told that so many had no accidents, so many had one accident, so many two accidents, &c. Can we from the *form* of this distribution learn anything about the causation of the accidents? We can put our imagination to work, invent explanations and then test them. There are three hypotheses which have occurred to most people. The first is that accidents really are a matter of luck, in which the quality of the victim goes for nothing. The case is supposed to be like that of tossing true coins; whether a coin shall fall head or tail depends upon a great many factors which, however, do not favour any one coin more than any other. The second obvious hypothesis is that, although before any accident has happened those exposed to risk are all alike, the having an accident differentiates the group so that those who have had one accident are more—*or* less—likely to have a second accident than those who have had none are likely to have a first accident. The third hypothesis is that, *ab initio*, the liability to accident varies from person to person. Each hypothesis must have occurred to any intelligent person. A step forward was taken when it was found that each hypothesis could be expressed algebraically and that the algebraical forms led to an arithmetical criterion of the probabilities of the several hypotheses. Mr. Udny Yule and I reached an approximate solution of this problem in 1919,[2 3] and our work has since been greatly improved and generalised by Miss E. M. Newbold,[4] whose admirable memoir was recently awarded the Guy Medal of the Royal Statistical Society.

A New Instrument of Research.

The approximate solution of the theoretical problem put into our hands a new instrument of research. The next step was to obtain adequate data for testing. This was a very difficult task and has occupied much of the time of several investigators for years.[5] Incidentally, it has led to great improvements in the keeping of accident records and has been of some little service to employers of labour in bringing to their notice the importance, in terms of efficiency, of individually trivial occurrences. So far as the original problem is concerned, it has been established that, while it is certainly not possible to draw hard-and-fast lines in ætiology, the third hypothesis—viz., that individual susceptibility is of primary importance—is the one most satisfactorily accounting for the facts. It further appeared that those peculiarly susceptible to minor accidents were also, on the whole, more prone to minor illnesses. Having reached the conclusion that proneness to accident tends to be an individual peculiarity, the next point was to ascertain whether this character were correlated with some other physiological or psychological character which could be independently measured. If so, it might be possible, *before* exposure to risk, to say who were likely to be dangers to themselves or others. Here, too, progress has been made, particularly by Farmer and Chambers.[6] They applied various physiological and psycho-physiological tests to a large number of subjects and found, in their final weighted results, a difference of 48 per cent. in the accident rate between those above and those below the averages in the tests. These researches are still in their infancy; no tests yet used have shown a sufficiently high association with the elusive quality—or group of qualities—determining accident-liability to be of much practical use in vocational selection. But the future is promising. Work on other lines, developing from the Board's investigation of telegraphists' cramp,[7] has also brought us to the conviction of the need to assess the psychological make-up of the worker, to seek to *measure* it. The accident problem has thus fallen into its place in the general scheme of seeking to measure all things, not only the lighting and heating of the factory, not only the output of the worker, but his personality. Speaking as a statistician, I should say that ten years rather close association with this work has not indeed shaken my natural faith in the value of the statistical instrument, but has convinced me that, while the statistician can nearly always be a useful critic, he can only do useful research work as one of a team, neither the master nor the servant of his colleagues. Those having expert knowledge of industrial conditions may blunder in statistical logic, those skilled in statistical methods may misapply them for lack of practical knowledge of the material used. This was quickly

realised in England, and the investigations of the Industrial Fatigue Research Board have always been coöperative. Often a special committee has been appointed, upon which clinicians, physiologists, statisticians, employers, and employed have met upon equal terms, and *always* a research report has had to run the gauntlet of criticism by the different experts mentioned. Of the value of this system in bringing about mutual understanding of methods and points of view I shall not speak; but one result I must notice for it is relevant to my theme. Intimate contact with those actually engaged, whether as employers or employed, in industry or commerce, has made us—if I may be permitted to reckon myself as an investigator—very reluctant to draw general conclusions or to lay down the law for any industry *as a whole*. A third year student can classify "cases" but a practitioner must treat *patients;* the investigator of industrial conditions discovers that even within a highly specialised craft the same verbal description covers disparate conditions. When the craft is not highly organised, this difficulty of being sure that what one has observed is really representative of the "universe of discourse" is still greater; yet it is just in these industries that knowledge is most needed.

Application to the Laundry Trade.

A good example is provided by Miss May Smith's "Studies in Laundry Trade." [8] One is dealing with a very important occupation employing a large number of people, but the conditions of employment are almost infinitely variable.

"Only one generalisation seems to be warranted with regard to the laundry trade as a whole—namely, that if a factory calls itself a laundry, then its main occupation is washing soiled linen and clothes. Nothing else can be taken for granted. The building may vary from a modern specially designed laundry with the latest machinery, ventilation appliances, rest and mess-rooms, to a converted house, shop, or stable, where all reconstruction has to be modified by the exigencies of the original building and where there is little or no room for expansion or modern requirements; between these two extremes there is every grade of adequate or inadequate building. Proprietors and managers, like the buildings, represent practically every social class and type of education and ability, and while we cannot say quite as much with regard to the workers, still in many laundries there exist side by side relics of the old washerwoman of a previous generation with the latest product of high-class factory girl. Turning to plant, the same diversity prevails; on the one hand is the firm anxiously distrustful of the effects of machinery on clothes and wishful to do as much of every process by hand as is compatible with its conditions, while on the other hand is the firm that eagerly tries every new appliance and scraps any machine that can be superseded by a better."

In these circumstances the research worker must first seek to discover whether the occupation when followed under reasonably good environmental conditions is inherently detrimental to health and fitness. Miss Smith took this course; her actual studies were made, for the most part, in reasonably well-equipped laundries, and there she was able to demonstrate large individual variations of efficiency and to show how improvement might be effected. Her measurements of atmospheric conditions covered a wider range of factory types, and in this matter—since the method, that of Dr. Leonard Hill, had been used in other industries—some comparisons were possible. It appeared that the atmospheric conditions of laundries compared unfavourably with those of some other industries—for instance, boot and shoe shops; the cooling powers were usually inadequate.

No General Conclusions Justified.

One would naturally wish to correlate these latter results with measures of sickness incidence, but for this adequate data were lacking. All Miss Smith was able to do was to obtain returns from 23 firms of time lost through three winter and three summer months. The data related to only 1144 workers, and all that can be said is that the percentage of time lost owing to illness—which varied from 1·0 to 1·8 per cent. of the total possible working hours—is certainly not greater than in occupations usually supposed to be healthy.

This research seems to me a good example of the method one should adopt in such cases. Some not unimportant discoveries have been made, means of minor improvements are suggested, and a further contribution is made to the knowledge of the general psychological factors of industrial efficiency. But neither the author in her text nor the Industrial Fatigue Research Board in their preface felt justified in generalising the results to cover the trade as a whole. I have quoted what seem to me convincing reasons in favour of this reticence. It might be added that it is not yet possible—it may never be possible—to compile uniform morbidity records having the *workplace* as the unit of classification for such an industry. Indeed, even when we have had to deal with highly organised and localised crafts, such as the textile trades, the compilation and standardisation of such records has been a costly and difficult undertaking. At present we really know nothing of current sickness rates in the laundry trade in England and Wales. One seems, therefore, forced to conclude that we do not know enough about the subject to draw *any* general conclusions, and so turns with a certain curiosity to an essay upon laundries recently issued by the International Labour Office. It might be that, at Geneva, data based upon continental experience had been assembled which had escaped the notice of the Industrial Fatigue Research Board.

A Geneva Brochure.

The International Labour Office's "brochure" on laundries forms No. 127 [9] of a series under the general title Occupation and Health, having the subtitle Encyclopædia of Hygiene, Pathology, and Social Welfare, Studied from the Point of View of Labour, Industry, and Trades. The cover records the names of an imposing list of expert collaborators, but this particular "brochure" (an article of six pages) carries the footnote: "According to an original report by Dr. L. Carozzi (I.L.O.), revised by the Correspondence Committee on Industrial Hygiene of the International Labour Office," which may perhaps mean that Dr. Carozzi, rather than the expert collaborators, should have the credit. The same footnote is attached to a "brochure" (four pages) upon Candles (Manufacture of) so that Dr. Carozzi's energies cover a wide industrial field.

The "brochure" opens quietly with some linguistic information and a warning that "there is an exceedingly wide range of method followed in this industry," while a paragraph headed "Dangers-Pathology," begins with the caution that "it is difficult to gauge accurately the effect of this industry on the health, since most of the diseases to which their occupation renders laundry workers liable are such as might equally well proceed from other causes. Certain investigations and statistical enquiries have shown health conditions in this industry to be in general satisfactory as compared with other industrial work." The syntax may be doubtful and we may regret that the investigations and statistical inquiries are not more closely specified, still this exordium hardly prepares us for the grisly catalogue which follows. It seems that the work and conditions of laundries "undoubtedly provoke and aggravate certain forms of disease." Varicose veins are easily developed, ulceration and flat-foot are common evils, while "the working of a foot-pedal, shaking and wringing linen, &c., are apt to exercise a bad effect on the genital organs." Eczemas and skin eruptions are common. Nails are loosened by "daily work in alkaline solutions," mycosis of "the external canal of the ear, due to *Aspergillus nigricans* or *flavescens*" may cause "marked irritation." Again, "affections of the upper respiratory passages are to be ascribed to steam and to the alkaline fumes present, which dry the throat, give rise to thirst, and often lead to habits of intemperance." This disquieting information is drawn from uncharted wells of truth known to Dr. Carozzi. Upon the subject of tuberculosis we

have a little more detail. We are first told of an authority who asserts that "tuberculosis is very widespread in this industry" and that "incipient forms of it are not uncommonly diagnosed and treated as anæmia."

The same authority, evidently a man of original mind whose name should have been disclosed, has actually drawn attention to "the part played by heredity and infection" and helpfully suggested that 'many of the victims are widows of consumptive husbands forced to take up the work in question in support of themselves and their families." This is interesting but perhaps a little inconclusive, and Dr. Carozzi, rightly, felt that some statistical verification would be expected—not of the particular fact about the widows of consumptives, which is clearly a stroke of individual genius, but of the general fact that tuberculosis is exceptionally prevalent amongst laundry workers. For England we are provided with a table introduced by these words: 'The following table shows the prevalence among workers in this industry of ulcers on the legs and pulmonary tuberculosis as compared with other women workers, the records being those of two infirmaries in *England*."

I reproduce the information contained in the first two lines of the table. We are told that in the first infirmary in the year 1899 (information is confined to 1899 and 1900) the "number of workers" consisted of 247 laundresses and 1171 other workers, 36 of the former and 50 of the latter had ulcerated legs, percentages of 1·5 and 4·3, 21 of the former and 63 of the latter had pulmonary tuberculosis, percentages of 8·5 and 5·3. In the next year the percentage of laundresses with ulcerated legs rose to 13·6, but that of other workers sank to 3·6.

This table and its description neatly illustrate some elementary mistakes. Dr. Carozzi either does not know that north and south of the Trent the word infirmary has a different meaning or supposes that the difference does not matter. If his infirmaries were *poor-law* infirmaries, *solvuntur tabulæ risû*. The highly selected sample of the sick cared for in parish infirmaries is not in respect of occupation, age distribution, or ailment typical of the working-class population. Even if the infirmaries were really hospitals, the select character of the hospital population would still invalidate the generalisation of the results. When it is further noted that the data are nearly 30 years old, that the age distributions are not given, and that percentages are based once upon six and three times upon seven cases, the reader will agree that this is indeed strange evidence to be circulated by an international organisation.

Dr. Carozzi cites other statistical evidence of less dubious origin and, in doing so, makes it clear that he is unfamiliar with medico-statistical methods. Thus he writes that "In the United States the mortality-rate for tuberculosis is only 16·3 per cent. for both sexes." This being a rate of mortality about equal to that of London in the year of the Great Plague, one might suspect a misprint, but the juxta position of a table of *proportional* mortality (the entries in which, if correct, would give a proportional mortality, for ages 25–65, from tuberculosis of between 16 and 17 per cent.) suggests that Dr. Carozzi does not mean *rate of mortality* at all, but *proportional mortality*. This follows also from his citation of Bezançon. According to Dr. Carozzi, Bezançon found that amongst laundry workers 26 to 30 per cent. of the general mortality was due to tuberculosis, a finding which, Dr. Carozzi supposes, warrants the statement that "the tuberculosis mortality is high." As the age distribution of the decedents is not given, it warrants no such statement. It would be a high proportion if the age constitution of those exposed to risk were that of the general population; it would be a low proportion if they consisted mainly of young women. For instance, in England and Wales in 1927, 89,987 women died between the ages of 15 and 65 years, of these 14,049, or 15·6 per cent., of tuberculosis. Between the ages of 15 and 45 years 34,845 died, 11,188, or 32·1 per cent., of tuberculosis. Proportional mortality figures have little value unless the age distribution is provided. *A fortiori*, to compare the unstandardised proportional mortality figure of a particular disease based upon one occupation with that from another occupation is wrong. Even when the age distributions are similar, the proportional mortality of a disease may increase although the rate of mortality decreases in passing from one occupational or social group to another. For instance, in the Registrar-General's evaluation of occupational mortality for 1921–23, 35 per cent. of the deaths in the age-group 25–35 in Social Class II. were attributed to phthisis; in the lowest Social Class V. 32·4 per cent. were so attributed. But the death-rate from phthisis was 161 per 100,000 living in this age-group in Social Class V., 132 per 100,000 in Social Class II. There is, of course, no inherent reason why the two indices should move together. Actually, when we confine ourselves to occupations of the same economic grading, they tend to do so, and the proportional mortality figure may, *faute de mieux*, be a useful pointer to the existence of special conditions. Even when different economic groups are compared, there is usually an increase of proportional mortality from tuberculosis as one descends the social scale and also an increase of mortality-rate. As Collis and I pointed out,[10] the proportional index is really of some value if used discreetly. As used by Dr. Carozzi it is worthless; he has not made it even faintly probable that *any* class of laundry workers suffers more from tuberculosis than the general population.

An Important Principle at Stake.

If this is the character of the sections of the "brochure" where statistical justification is attempted, it is surely needless to pillory *obiter dicta* of writers cited without any statistical justification. Indeed, the reader may well ask why I direct attention to this compilation at all. In fact these obvious defects make the article less dangerous than it might have been. With a little more literary skill and a little better staff work at Geneva, the blunders which have, I hope, amused the reader would never have reached the printer; but the "brochure" would have been as essentially unscientific as it is now. Indeed, an important principle is at stake. Anybody who has served in an official department knows how great is the temptation—often the result of pressure from without—to undertake "authoritative" expositions of scientific questions. It is not pleasant for an individual, it is still less pleasant for a department to admit that guidance cannot be given upon a subject of practical importance for lack of knowledge. But in a department charged with administrative duties, those responsible know that the scorn of journalists is easier to bear than the troubles which would be created by ill-grounded generalisations leading to a demand for action. One cannot easily picture the permanent head of a British Ministry who would give an *imprimatur* to such a report as Dr. Carozzi's. The cost of typing letters to indignant proprietors of laundries and of re-glazing windows broken in Whitehall by intemperate employees would be too heavy.

But the direct administrative responsibilities of the International Labour Office are not so harassing. Besides, few of the laundering widows of consumptives, or the victims of enteroptosis (a "prevalent" affection), cardialgia, kidney trouble, ptosis, retro- or ante-flexion of the uterus, dysmenorrhœa, hysteria, and anæmia (which are "common" effects) would be well enough, after the long and expensive journey to Geneva, to break the windows of the International Labour Office.

Hence there is a strong temptation to the staff of the International Labour Office to be voluminous and encyclopædic in their publications. But the temptation should be resisted or intelligent employers and employees will conclude that industrial hygiene as expounded by members of our profession is really only a poor kind of journalism. There are some branches

of applied medical science wherein the methods of research have been standardised for a sufficient length of time for it to be possible for an able medical official sitting in a library to prepare a useful summary of methods and results. Of very few subdivisions of industrial hygiene is this yet true; we need more careful field investigations, not compilations of *obiter dicta*.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Scottish Hospitals under the New Bills.

Major Walter Elliot, Parliamentary Under Secretary of State for Scotland, along with the officials of the Department of Health, met the Voluntary Hospital Liaison Committee a few days ago. This committee, it will be remembered, was appointed some months ago on the suggestion of the Secretary of State, to act as a liaison between the department and the voluntary hospitals. The meeting examined the position under the new Bill, and considered suggestions. It was unanimously agreed by the Liaison Committee that the poor-law stigma should be removed from hospital treatment, and that, therefore, the public bodies should have the necessary powers to provide hospital treatment apart from the poor-law. It was essential, however, that full and adequate safeguards should be made to protect the voluntary system, and the attention of the meeting was mainly directed to finding a form of words to achieve this purpose. The departmental representatives and the Liaison Committee decided to draw up a form of words that would give the necessary powers while safeguarding the position of the voluntary hospitals. Another meeting was to be held shortly.

Now that the Aberdeen experiment is under way there ought to be no great difficulty in adjusting a form of words that will meet all interests. The voluntary hospitals are anxious to coöperate in every practicable way with the local authorities and the Secretary of State. The recent experience of Glasgow in connexion with pneumonia and influenzal pneumonia had made manifest to the voluntary hospital authorities how important it is to maintain a good understanding with the public bodies. This will become even more manifest when the health authority is the "predominant partner" in the management of all sickness, but particularly sickness attributed to any form of infection. The experiment made with Stobhill by the poor-law authorities of Glasgow has paved the way for the all-round coöperation of the Glasgow hospitals. A similar movement is proceeding in Edinburgh. It is generally expected that all difficulties will disappear.

The Juvenile Delinquent.

In the circulars issued by the Scottish Office for magistrates and justices regarding the reports of the Departmental Committee on the Protection and Training and on Sexual Offences against Children, prominence is given to the necessity for careful medical examination of the juvenile and the juvenile-adult delinquents. The intention is to secure that any form of mental defect shall not be treated as mere criminality. It is laid down that the medical examiner selected by the juvenile court should, if possible, be one who has special qualifications for this class of work, and it is desirable that he should have some special experience in dealing with defective children or young persons. In most cases services of school medical officers will be readily available for this purpose. It is well that this point is emphasised, because, among recent developments, the non-medical psychologist has tended to become the dominant power. But it is well known that in many forms of mental defect, the psychological condition is merely a symptom either of imperfect physical development or of the positive presence of disease in glands or other hormonic structures. When education alone is in question, the lay psychologist has a large part to play, and the majority of delinquents demand the services of both types of expert.

The Scottish Education Department has issued a special circular on the report of the Committee on Sexual Offences. Mr. McKechnie, the new Secretary of the Scottish Education Department, was himself a member of that Committee, and, as one might expect, the circular gives evidence of an intimate and comprehensive knowledge of the problems. Mr. McKechnie lays great stress on the moral health of the children, and places character building among the primary duties of the education authority. He urges the importance of establishing social contacts of every desirable kind—for example, definite Church connexion, organised play centres, and playing-fields. In particular the department's circular suggests that the names "reformatory" and "industrial" shall be dropped from the description of schools. Although this cannot at present be done without an amended legislation, the department will henceforward call these schools training schools or have them known by a distinctive name. Also, it is suggested that as far as possible the children should attend the ordinary day schools in the district. Stress is laid on the need for recreation amenities and freedom, and above all for constructive education.

In connexion with the delinquent there is one important point—that the medical and school records should be available for the use of the court and that the education authorities should be willing to furnish these. These two circulars now formally bring the treatment of the juvenile delinquent on to a better administrative plane. They deserve the closest study by everyone concerned with this difficult group of problems.

The Influenza Epidemic in Glasgow.

The outbreak of influenza in Glasgow has been relatively sudden; there was nothing in the December figures to give warning of its approach. In fact, according to Dr. MacGregor's bulletin, the death-rate of 13·1 per 1000 in that month was remarkably low for the season; last December it was 18·7. Indeed, the 1928 death-rate as a whole was low—viz., 13·7, the same as the two lowest recorded years 1922 and 1927. Nor were the December pneumonia deaths exceptional, being 197 as against 298 for 1927; the other respiratory deaths being 94 as against 152. The epidemic was not preceded by any calculably greater prevalence of such simpler respiratory affections as acute tonsillitis. Reports of cases came in rapidly during the later days of a rather dense and continuous fog, which was followed by dull and cold weather, with mist at certain parts of the day. Other parts of Scotland were affected in more or less the same way, but Glasgow fogs are usually more severe. Fog and low temperature together, coming at the same time as the influenza, have greatly increased the incidence of acute pneumonia as a complication. Unlike the serious outbreak in the first quarter of 1927, this outbreak is not characterised by any peculiar virulence of the influenza itself; the symptoms are catarrh of the

upper respiratory passages, with moderate fever, lasting from three to five days, with the usual headache, general pains, malaise, and slow convalescence. There has been a good deal of laryngitis. The increase in the death-rate is due to the acute pneumonia accompanying or following the actual attack of influenza. The influenza epidemic began in the week ending Jan. 5th, when the general death-rate was 19·15 per 1000. In the week following it rose to 31·2 and 43·2, much as in March and April of last year. The actual deaths for these three weeks were: influenza, 14, 49, 149; bronchitis, 39, 73, 114; pneumonia, 59, 118, 187; other respiratory diseases, 4, 13, 14; total deaths, 116, 253, 464. The age-incidence is striking; children under 5 have suffered most from the respiratory group (excluding influenza). Thus, while the under-5 deaths from influenza were only 1, 0, and 15 in the three weeks, the figures for pneumonia and bronchitis together were 24, 62, and 107, with only one under-5 death from other respiratory forms. It should be added that "pneumonia" probably covers lobar consolidation, congestion of the bases, bronchitis and heart disease (especially in the old), and broncho-pneumonia. Some 600 to 700 beds are in use for pneumonia and the like in the municipal hospitals and no doubt, as formerly, further beds will be made available.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The General Death-rate.

THE death-rate for the year 1927 has just been reported by the Chamber of Commerce to be 11·4 per 1000 living. This compares favourably with the rate of 12·2 for the year 1926. All but five of the 41 States in the registration area showed some fall in their rates. Those showing increases are all young States, in which the age-constitution of the population is probably not yet stable, and the first three are also the resorts of invalids. The States in question are Arizona, California, Colorado, Oregon, and Wyoming.

Deaths from Snake-bite.

During the past year 570 cases of snake-bite have been reported to the Antivenin Institute of America in Philadelphia. Of these 401 received serum, of whom 11 died. Among the remaining 169 there were 16 deaths. Copperheads were responsible for the largest number of bites, 159 being reported from 21 States between April and November. The cotton-mouth moccasin bit 38, the pygmy or ground-rattler 171, and the massasagua or swamp-rattler 2. Of the true rattlesnakes (genus Crotalus) the Texas diamond-back bit 95, the timber rattlesnake 40, the prairie rattlesnake 38, Pacific 27, Eastern diamond-back 11, and sidewinder 4.

Influenza.

The public health service estimates that there were one and a quarter million new cases of influenza in the week ended Dec. 22nd. The disease has been very general this winter, though not particularly fatal. A definite epidemic was noted on the California coast in the second half of November. It appears to have spread rather slowly, until it has now reached the Eastern sea-board. In some sections children and young adults are said to be chiefly affected, in others people of middle age. It is probable that many more cases occur than are reported and that, if all cases were known, no age-group would be found to have escaped. Surgeon-General Cumming speaks of the possibility of a second epidemic wave with higher fatality.

Prof. John J. Abel and Dr. H. Jensen, of Johns Hopkins Hospital, announce that they have isolated the active principle of insulin in the form of a crystalline protein of relatively simple composition.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Health of the People.

SOME idea of India's vast public health problems may be obtained from the report for 1926 of the Public Health Commissioner with the Government of India which has just come to hand. India's death-rate in 1926 was 2½ times that of England and Wales, her infant mortality-rate 2⅔ times. In India the expectation of life at 5 is approximately 35 years, and at 20 is about 27, as against 54 and 41 respectively in Great Britain. Generally it may be accepted that an Indian's expectation of life at birth is less than half the average figure for a European. Cholera was responsible for 59,000 deaths in Bengal alone. During the year 196,000 deaths from plague were recorded in British India; of these no fewer than 108,000 occurred in the Punjab and 57,000 in the United Provinces. In 1926 the infant mortality-rate per 1000 births for British India was 189, while in several towns approximately half the infants born died within the first year of life.

The medical inspection of school-children is in a very backward state, but such figures as are available indicate that the physical fitness of this class of the population is very unsatisfactory. In the administration report of the School Committee of the Bombay Municipality for 1926–27 some significant figures are given. There were 25,332 children inspected, of whom 18,786 were boys and 6546 girls. Of these 17,059 were examined for the first time and 8273 were re-examined as they had been found diseased in the previous year's inspection. Of those examined for the first time only 40 per cent. of the boys and 34 per cent. of the girls were found to be free from disease or defect. In other words, 60 per cent. of boys and 66 per cent. of girls were medically wanting. Malnutrition was the most prevalent condition (27·8 per cent. of boys and 32·2 per cent. of girls). Defective teeth were found in 26 per cent. and 27·5 per cent. respectively, and other common defects were those of the throat, nose, and eye, enlarged spleen (9 per cent.), enlargement of lymph glands, contagious skin diseases, and lung diseases.

Medical Research in India.

The annual Conference of Research Workers, held recently at the School of Tropical Medicine and Hygiene, Calcutta, under the presidency of Major-General T. H. Symons, Director-General of the Indian Medical Service, was attended by delegates from various parts of India representing different aspects of medical research, public health, and allied interests, to the number of about 50. Two schemes at present under consideration by the Government of India were discussed. One of these concerns the proposed establishment of an All-India Institute for Education and Research in Public Health, towards which the Rockefeller Foundation in America is offering assistance. This institute will be built close to the present Calcutta Tropical School, with which it would be associated. The second scheme is the result of the report of the Fletcher Committee, which suggested the establishment of a Central Institute of Medical Research at Dehra Dun. The influence of these two schemes on the activities of the Indian Research Fund Association was closely scrutinised. The researches carried on by the association during the past year were reviewed, and it was found necessary to stop a few of the inquiries and to limit activity of others on account of shortage of available funds. This still leaves a comprehensive programme of research into most of the principal diseases of India. The secretarial duties of the Conference were in the hands of Lieut.-Colonel F. P. Mackie, I.M.S., officiating Public Health Commissioner with the Government of India.

Tuberculosis in Bengal.

The grave menace to public health caused by tuberculosis in Bengal is brought out in a recent lecture by the Director of Public Health in that province. There is evidence that tuberculosis is exceedingly widespread in Bengal, not only in the towns but also in the rural areas. Investigations suggest that something approaching 10 per cent. of the total mortality in several districts is due to phthisis, and there are grounds for believing also that this is by no means an excessive estimate. In the case of Calcutta about 8 per cent. of all deaths are ascribed to tuberculosis, but Sir Leonard Rogers, as a result of a careful examination of the records of post-mortem examinations made in connexion with the Calcutta hospitals during the past 22 years, has shown that no less than 17 per cent. of the total deaths were due to tuberculous disease, and that in 25 per cent. of cases examined signs of tuberculosis were present.

Public Health Services.

INFLUENZA.

THE weekly returns of deaths attributed to influenza in England and Wales, of which a summary follows, do not show any increase abnormal for the time of year. In Scotland the deaths from influenza in the week ended Jan. 19th numbered 179, being 123 more than in the previous week. Of these 179 deaths, 151 occurred in Glasgow, about which our Scottish correspondent gives some details. In Northern Ireland an unusual number of deaths from influenza are reported in Belfast, where the prevalence of the disease has been manifest among the constabulary and in the transport service. Our Dublin correspondent writes that there is as yet apparently only one serious outbreak of influenza in the Irish Free State—namely, in Waterford. The Department of Local Government and Public Health has, however, acted wisely in issuing a circular to all sanitary authorities detailing the precautions to be taken against the spread of the infection. An educational leaflet has also been issued which relates the modes by which infection is spread, and advises the avoidance of all overcrowded houses of amusement and overcrowded public conveyances. Advice is given to those attacked to retire to bed at once and seek the aid of a doctor, and also to avoid any undue exertion for a considerable time after the attack. In the circular to sanitary authorities it is suggested that children from infected houses should not attend school, and in cases of epidemics in rural areas the schools might be closed. Patients suffering from influenza should be isolated early, and if a patient is nursed at home he should have a separate room. The danger of spitting is emphasised. Those suffering from influenza or catarrh should realise that they may convey infection to others with fatal results. The notification of pneumonia and influenza-pneumonia has been rendered obligatory by an order of the Department.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 12TH, 1929.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 213 (last week 188); scarlet fever, 2221; diphtheria, 1245; enteric fever, 28; pneumonia, 1936; puerperal fever, 37; puerperal pyrexia, 120; cerebro-spinal fever, 9; acute poliomyelitis, 4; acute polio-encephalits, 1; encephalitis lethargica, 19; dysentery, 5; ophthalmia neonatorum, 81. No case of cholera, plague, or typhus fever was notified during the week.

The cases of small-pox were notified from the following 17 counties: London, 6; Bedford, 1; Chester, 2 (Ellesmere Port); Derby, 31; Durham, 45; Essex, 8 (West Ham); Lancaster, 13; Leicester, 13 (County Borough); Northampton, 10 (County Borough, 9); Northumberland, 16 (Tynemouth); Nottingham, 1 (Worksop R.D.); Soke of Peterborough, 8; Stafford, 1 (Stoke-on-Trent); Wilts, 1 (Swindon); Yorks, West Riding, 33; Glamorgan, 15 (of these Merthyr Tydfil 10), Monmouth, 9.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Jan. 15th-16th was as follows: Small-pox, 32 under treatment, 1 under observation; scarlet fever, 1984; diphtheria, 2153; enteric fever, 19; measles, 45; whooping-cough, 608; puerperal fever, 26 (plus 10 babies); encephalitis lethargica, 75; poliomyelitis, 4; "other diseases," 32. At St. Margaret's Hospital there were 19 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was 1 death from small-pox, 2 (0) from enteric fever, 28 (0) from measles, 8 (2) from scarlet fever, 59 (13) from whooping-cough, 50 (10) from diphtheria, 58 (15) from diarrhœa and enteritis under two years, and 122 (24) from influenza. The figures in parentheses are those for London itself.

The number of deaths from influenza during the previous seven weeks were 49, 56, 60, 61, 69, 83, and 99 respectively—a slow and even rise. The deaths in the week under review occurred largely in the midland and northern counties: Brimingham 6, Liverpool 5, Leeds 4. Glasgow reported 50 and Belfast 7, during the same week. The two deaths from enteric fever outside London occurred at Leyton and Newcastle-on-Tyne. Liverpool reported 7 deaths from measles, Hull and Sunderland 3 each. Leeds reported 4 deaths from whooping-cough, Salford, Oldham and Burnley 3 each (Glasgow 7). Five deaths from diphtheria occurred in Plymouth, 4 in East Ham, and 3 in Nottingham. Manchester reported 6 deaths from diarrhœa, Liverpool 5, and Salford 4. One death, provisionally classified to small-pox, was assigned to Halifax C.B.

The number of stillbirths registered during the week was 249 (corresponding to a rate of 36 per 1000 births), including 45 in London.

SOCIETY OF BRITISH NEUROLOGICAL SURGEONS.

THE fifth meeting of this Society was held in London in December under the presidency of Sir Percy Sargent. A visit was paid to Guy's Hospital, where Mr. Lancelot Bromley operated, turning an osteoplastic flap by de Martel's method. The Society was addressed by Dr. A. F. Hurst on the Cause of Trophic Disturbances in Nerve Injuries, and Dr. C. P. Symonds showed cases including radiograms of a calcified angioma of the brain, to which Mr. Bathe Rawling was able to exhibit a parallel. Dr. Symonds further exhibited a case illustrating tonic innervation of the hand in a young woman clinically diagnosed as a congenital aneurysm, and a case of cervical rib with cerebral embolism. The relationship between vessel compression and embolism was discussed. Mr. Bromley presented a female patient from whom he had enucleated a spinal tumour. Persistent contractures of the hamstrings had necessitated tenotomies, so successfully carried out by Mr. W. H. Trethowan that the patient was now able to walk up and down stairs. The meeting was resumed in the afternoon at the National Hospital, Queen-square, where Sir Percy Sargent opened a discussion on the Radium Treatment of Cerebral Tumours, and Mr. J. P. Ross described the technique and results so far obtained in a small group operated upon at St. Bartholomew's Hospital. This subject, theoretically so full of promise for the glioma patient, was fully discussed by other members. Dr. J. G. Greenfield's paper on the Hæmangiomatous Cysts of the Cerebellum (Lindau's tumour) preceded this, illustrated by a series of cases in which the pathology of the condition was built up step by step. Other papers read were: Prof. Archibald Young's on Chordoma, Mr. Julian Taylor's advocating a more posterior approach than the classical London route to the root of the Gasserian ganglion, Mr. A. A. McConnell's on Mistakes in the Interpretation of Ventriculograms, and Mr. Lambert Rogers's on Elephantiasis Neurofibromatosa. The Society's dinner was held at the Langham Hotel with Mr. Donald Armour in the chair. On the following morning Mr. L. R. Broster divided the sensory root of the trigeminal nerve for neuralgia and showed a number of patients, including a young woman with a suprarenal tumour and virility (the second example of this unusual condition which he has placed before the Society). Dr. W. J. Adie read a brief paper describing cases of spinal and pituitary tumours and emphasised the importance of being on the watch for these latter in cases of non-syphilitic optic atrophy. Dr. A. B. Rosher contributed a talk on the chemistry and cytology of cerebro-spinal fluid, whilst Dr. G. Viner discussed the histology of the gliomas and showed a number of specimens.

"Audi alteram partem."

ASTHMA RESEARCH.

To the Editor of THE LANCET.

SIR,—Perhaps Mr. Frank Coke will forgive me if I take his letter in your issue of Jan. 19th as a text from which to plead for the serious consideration of the psychological aspect of asthma. He writes: "In the past those unfortunate people, the asthmatics, have been treated as neurotics, and their symptoms stigmatised as nervous manifestations, and they were told they were incurable." It is news to me that such a state of affairs once existed, but the phrases "treated as neurotics" and "stigmatised as nervous manifestations," suggest that he refers to an era before the development of modern psychopathology. He justifiably holds out hope of cure from the study of biochemical processes and his list of methods of cure—so divergent that it is difficult to conceive a theory of pathology common to all—is far from complete. From my own knowledge I can add cauterising the nasal septum, avoiding feather pillows, Christian Science, psychotherapy, and a visit to the battlefields of France—vagaries sufficient to suggest some factor not to be elucidated by research limited to biochemical phenomena.

Psychopathologists have of necessity received sufficient training to follow the work of Mr. Coke and his colleagues with reasonably intelligent interest. They have, in addition, the advantage of practical experience of the influence of mental processes, often unsuspected by the ordinary clinician, in producing emotional states which, in turn, find expression by alterations of physiological function. Some of them have recorded cases of asthma in which the sequence of pathological events was of this nature and, in spite of Mr. Coke's pessimism, they even hold out hopes of cure by psychological means. I myself am acquainted with people who actually claim to have been cured of asthma by some kind of psychoanalysis. Yet psychopathologists find no difficulty in reconciling their views with biochemical theory; some theory of the kind is necessary, for by their own hypothesis a physiological process is set in motion, and it must follow a biochemical path. They will even admit that to direct our therapy towards the physiological process is often justified by results.

We must accept as facts of observation both the biochemical phenomena and the disappearance of asthma after psychological treatment, treatment which is not haphazard but which often throws light upon the *why* of the situations that have called up the attack, and it is probable that the correlation of these two groups of facts may furnish the key to the whole problem. Instead of a collection of abnormalities to be interpreted only as freakish manifestations of a biochemical Puck, we have now a reasonable assumption of cause and effect that may be made a basis of research. As a point of attack we might start on the relation between hysterical dermatographia—a physiological sign of pathological anxiety—and the urticaria group or the dermal reactions of the asthmatic, not omitting a psychological study of the sufferers.

Those who regard an asthma patient as something more than a collection of test-tube reactions and conditioned reflexes will, in the interests of coöperation and understanding, protest against the point of view implicit in Mr. Coke's words as quoted above. I may be doing him an injustice, but I read into them that he uses "neurotic" as a term of reproach and regards any psychological approach to a disorder as an attack upon the moral integrity of the sufferer. This mental attitude still survives, and we often read in case reports such phrases as "the patient was in no way neurotic," the only information given by the phraseology being that the reporter does not appreciate possibilities. Would he recognise (or stigmatise) as "neurotic" the hardworking and overscrupulous type described in the leading article in the same issue? This protest concerns the nervous patient generally. With regard to the main question, it is not too much to say that any worker upon asthma who pushes aside the help offered by psychopathology deprives himself of an essential weapon.

I am, Sir, yours faithfully,

MILLAIS CULPIN.

Queen Anne-street, W. Jan. 21st, 1929.

THE TREATMENT OF HÆMORRHOIDS BY INJECTION.

To the Editor of THE LANCET.

SIR,—I note with surprise the renewed advocacy of the submucous injection treatment of hæmorrhoids. I recall a joint meeting [1] of the American Proctological Society and the corresponding subsection of the Royal Society of Medicine, held in London on July 9th, 1924, when, following a very able paper by the late Mr. Græme Anderson, and after a full discussion, the general opinion was that the method was only of use in simple uncomplicated cases, and that recurrence followed in some 50 per cent. of these. How is it possible for such a method to deal with those cases, very common, in which there is a large protruding œdematous mass of rectal tissue, showing bleeding ulcerative piles higher up? I feel certain that if Mr. Christopher Howard and Mr. A. S. Morley will try the treatment by galvanopuncture into the vein itself, described by me before the Harveian Society in October, 1925, and afterwards published,[2] they will never use any other method. I am, Sir, yours faithfully.

Harley-street, W., Jan. 21st, 1929. W. S. WHITCOMBE.

MYOFIBROSITIS.

To the Editor of THE LANCET.

SIR,—In his address on Myofibrositis as a Simulator of Other Maladies, published in your issue of Jan. 19th, Prof. G. R. Murray is highly interesting and informative, but he does not give any evidence of the symptoms mentioned being caused by fibrositis. However tempted one may be to agree with him—and it would be impossible to prove that they were not so caused—Prof. Murray's readers would be grateful for definite evidence of fibrositis being the fiend that causes all this trouble. Positive evidence is much more satisfactory than reasoning by exclusion.

I am, Sir, yours faithfully,

SHEFFIELD NEAVE.

Ingatestone, Essex., Jan. 21st, 1929.

TEACHING OF MEDICAL HYDROLOGY.

To the Editor of THE LANCET.

SIR,—Owing to the proposal to make spa treatment available for insured patients suffering from rheumatism and kindred ailments, it is probable that many medical men in this country would be glad of the opportunity of learning something of a method of treatment which is more familiar to the medical profession on the Continent than in Great Britain. Until quite recently the only means of obtaining information on these subjects was to visit one of the spa hospitals, but in 1923 a Committee was formed, composed of representatives of the chief spas of Great Britain, and from London, for the purpose of giving instruction in medical hydrology in the universities and medical schools of Great Britain. This function the Committee still performs, but it is thought that some medical societies not connected with teaching centres might care to hear lectures

[1] See THE LANCET, 1924, ii., 117.
[2] Brit. Med. Jour., 1925, ii., 992.

on this subject. The Committee has selected as lecturers a number of medical men who have expert knowledge of the subject, and I shall be glad to forward a list of their names to the secretary of any medical society who may wish for further particulars.

I am, Sir, yours faithfully,

GEOFFREY HOLMES, M.B. Camb.,
Honorary Secretary,
The Committee for the Study of Medical Hydrology in Great Britain.

11, Ripon-road, Harrogate, Jan. 15th, 1929.

THE CAUSE OF SEA-SICKNESS.

To the Editor of THE LANCET.

SIR,—A good deal of controversy has raged in the medical press and elsewhere on the pros and cons of ocular sensation as a cause of sea-sickness. The following personal experience may have some bearing on the matter.

As a sailor I have experienced the sensations of sea-sickness sufficiently often to recognise them without any doubt or question, though fortunately, provided there is an adequate supply of food available to fill the gaps as created, I have not suffered severe incapacity. I have noticed similar sensations when trying to read in a corner seat with my back to the engine in a train, but I have never known any similar sensation in any shape or form while in a motor-car until Sunday last. On this occasion, I drove from Hammersmith Broadway to Roehampton through a dense white fog, which was drifting steadily almost at right angles across the road in front of us; and, after some half hour or so of groping along, the all-too-familiar sensations returned with sufficient severity to render it almost impossible to keep my seat, although I did manage to survive with a considerable effort.

In a still fog, such as one usually encounters in London, I have never known a similar sensation to the smallest extent, and can only conclude that in my own case at any rate ocular sensations must play a very large part in the production of the symptoms.

I am, Sir, yours faithfully,

Jan. 22nd, 1929. M.A., M.D.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

REASSEMBLY OF PARLIAMENT.

BOTH Houses of Parliament reassembled after the Christmas recess on Tuesday, Jan. 22nd.

HOUSE OF COMMONS.

TUESDAY, JAN. 22ND.

Report on Milk Prices.

Mr. ROBERT MORRISON asked the President of the Board of Trade whether the Food Council had now completed its report upon milk prices; and when it would be published.—Sir P. CUNLIFFE-LISTER replied: I understand that the preparation of the report has reached an advanced stage, but I cannot give a definite date for its publication.

Slum Clearances in Glasgow.

Mr. STEPHEN asked the Secretary of State for Scotland the total number of houses built in Glasgow last year under the slum clearance scheme and the corresponding figure for the previous year; and how many slum houses it was estimated remain to be dealt with.—Sir J. GILMOUR replied: The total number of houses completed in Glasgow under slum clearance schemes was 996 in 1926 and 838 in 1927. I am informed that the estimated number of slum houses in the city remaining to be dealt with is 13,000.

Slum Clearance Schemes.

Lieut.-Commander KENWORTHY asked the Minister of Health how many houses had been demolished under slum clearance schemes in the last four years; and how many persons formerly living under slum conditions had been re-housed under these schemes.—Sir KINGSLEY WOOD (Parliamentary Secretary to the Ministry of Health) replied: Information in regard to the matter referred to by the hon. and gallant Member is only available from April 1st, 1925. Between that date and Dec. 31st, 1928, the latest date for which particulars have been furnished, 8540 buildings have been acquired for demolition, 6002 buildings have been demolished, and 6949 new dwellings have been erected in connexion with slum clearance schemes. It is estimated that approximately 31,000 persons have been re-housed in these new dwellings.

Lieut.-Commander KENWORTHY asked if there was any prospect of these meagre operations being expedited.

Sir KINGSLEY WOOD replied that considerable progress had been made during the last few years, as local authorities were displaying more vigour in dealing with slum clearance schemes.

Obituary.

FERNAND WIDAL, M.D. PARIS,

PROFESSEUR AGRÉGÉ DE LA FACULTÉ DE MÉDECINE.

WE regret to announce the death from cerebral hæmorrhage on Jan. 14th at his *appartement* in Paris of Prof. Widal, whose name is everywhere familiar in connexion with the agglutination reaction.

Georges Fernand Isidore Widal was born on March 9th, 1862, at Dellys in Algiers, a small town, few of whose inhabitants are European, situated a mile or two east of Algiers on the coast. He received his medical education in Paris, and by his attainments and his application made a mark among his fellows in early life. He was an interne des hôpitaux in 1885, took his doctorate in 1889, and he was but 27 years of age when he published his treatise on Puerperal Infection, a work which showed that he possessed already a valuable power of bringing laboratory experience directly to the bedside. He became professeur agrégé in 1895, and in the following year he obtained world-wide fame by the so-called Widal test for the diagnosis of typhoid fever. The association of his name alone, however, with this test was an error. The discovery of the agglutinating action of typhoid serum and its application to the clinical diagnosis of typhoid fever occurred in 1896, and was the work of H. E. Durham, Max Gruber of Vienna, and Widal. A good deal of acrimonious discussion has taken place with regard to the respective merits of these workers, but there is little doubt now that the pioneer was Gruber. The first actual publication, with admitted acknowledgments to Gruber, was made by H. E. Durham. This was in January, 1896, and it was followed by two communications from Gruber and Durham in March of the same year. In Durham's first paper on the subject attention was directed to the possibilities of the agglutination method for the clinical diagnosis of typhoid fever, and this phenomenon was demonstrated by Widal on June 26th, 1896. Early in September A. S. Grünbaum (afterwards Leyton) published in THE LANCET (1896, ii., 806) a Preliminary Note on the Use of the Agglutinative Reaction of Human Serum for the Diagnosis of Enteric Fever, in the course of which he referred to Widal's work in terms which the French pathologist resented. Widal's own description of the significance of his researches followed in THE LANCET in November of the same year when he claimed his position as the author of the new method—viz., that of "serum diagnosis by which typhoid fever can be recognised almost

FERNAND WIDAL.

instantaneously by simply observing microscopically how the serum of a patient acted on a culture of Eberth's bacillus." The question of priority was thus challenged, but it is now seen to be of little significance and its phenomena are usually now termed simply the agglutination reaction.

Following on the developments in the diagnosis and prevention of typhoid fever, especially in sequence to discoveries in respect of typhoid vaccination, Widal achieved a reputation for original research which perhaps he hardly merited. He became one of the best-known medical men in Paris, being especially a prophet of the idea that science should be applied in practice, a doctrine which drew to him a very large following of young men, and which can hardly be called novel. But his clinical fame was truly earned, and will largely rest on his hospital work at the Cochin Hospital, where his classes were admirably organised and where his brief lectures invariably attracted large crowds. His laboratory work in the later phases of his career was of a desultory character; he showed extreme keenness in many directions, but can hardly be credited with any ordered researches. None the less he certainly enjoyed and deserved his great position as a physician, and his qualities as a man of the world stood him in excellent stead with the public.

Prof. Widal had been confined to bed for a week with an acute attack of gout when cerebral hæmorrhage proved rapidly fatal. He was buried at the cemetery of Montmartre on Jan. 17th, when the funeral address was delivered by Prof. Lemmière.

THOMAS BROOK, B.D., M.D., LL.D. Dub., who died at Biskra in Algeria on Jan. 7th, was a graduate of Trinity College, Dublin, in arts, divinity, medicine, and law. He was ordained in 1895 and after holding a curacy in Derbyshire and another in London returned to Dublin as acting chaplain to the Forces. This gave him the chance of studying law, and when next he returned to Dublin, after a period as Army chaplain at Malta, he graduated in medicine also. During the late war he served in France and Salonika, and on retirement from the Service in 1919 he was attached to the staff of the Ministry of Pensions for some time, later acting as medical officer to the Brigade of Guards at Pirbright. He had gone to Biskra for the benefit of his health, and died at the age of 58.

BY the death of ARTHUR HENRY HEADLEY HUCKLE, M.R.C.S., L.D.S., on Jan. 13th, Hastings loses a practitioner of high standing in the neighbourhood. An Australian by birth, he was born at Melbourne in 1871, and was a son of the late Frederick Thomas Huckle. He came to England as a child and was educated at Dulwich College and University College, London. He studied medicine at Guy's Hospital, and after taking both dental and medical diplomas was also called to the Bar. In 1904 he was appointed medical superintendent of the Hastings Borough Sanatoria, and in 1901 he joined the staff of the Royal East Sussex Hospital as honorary pathologist and dermatologist. Of late years he was medical officer of the Hastings and East Sussex venereal diseases clinic. Dr. Huckle married Grace, only daughter of the late Dr. Walter Farnfield, and his widow is left with one daughter.

HERBERT NORMAN EVANS, B.M. Oxf., who died at Seaford on Jan. 9th in his ninety-fourth year, was the eldest son of Dr. Herbert Norman Evans, of Hampstead, and was educated at Winchester and Exeter College, Oxford. Like his father and his grandfather before him, he adopted medicine as a profession, and after studying at St. Bartholomew's Hospital became M.R.C.S. Eng. in 1860. From 1864 until 1893 he practised in Hampstead, being appointed surgeon to the Hampstead Dispensary. On retirement he went to live at Seaford, and enjoyed remarkably good health until quite recently. Dr. Evans had been a good rifle shot, and joined the Volunteers in August, 1859, when the movement was started. He served for 33 years as a private in the 3rd Middlesex Regiment, his professional work preventing him from giving up more time. He was twice married and leaves four children.

THE death has occurred at Oswestry of ROBERT DE LA POER BERESFORD, M.D. Glasg., at the age of 86. Educated at Trinity College, Dublin, he also studied medicine at the University of Glasgow, where he graduated M.D. in 1871, having previously qualified L.R.C.P. & S. Edin. in 1869. In 1916 he took the D.P.H. of Liverpool University. Dr. Beresford went to Oswestry more than 60 years ago and for 59 years was medical officer for the town. He was a justice of the peace for Shropshire and mayor of Oswestry for two years.

JOHN HARRISON, M.R.C.S., who died at Braintree on Jan. 16th, qualified in 1882 after studying at Guy's Hospital, and was appointed coroner for North Essex over 44 years ago. During his term of office he held over 5000 inquests. Dr. Harrison was 72 years of age and was educated at Felsted School, where he was afterwards medical officer.

THE death took place on Jan. 14th, in his eighty-first year, at his home in Sheffield, of ALGERNON ARCHIBALD PAYNE, M.R.C.S., who was the oldest medical practitioner in the city. He qualified in 1877 after studying at Sheffield and St. Bartholomew's Hospital, and was in practice in Sheffield for over half a century. He was an authority on war medals and decorations and on British and foreign Orders, and in 1911 he published a book on this subject. He also wrote a history of the York and Lancaster Regiment.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At a congregation on Jan. 18th the following degrees were conferred:—

M.B. and B.Chir.—S. W. Savage and Fred Smith.

B.Chir.—Leslie Foulds, Edward Clayton-Jones, A. J. Dix Perkin, H. F. Bateman, L. T. Hilliard, and J. C. F. Lloyd-Williamson.

ROYAL INSTITUTION.—On Tuesday, Jan. 29th, at 5.15 P.M., Prof. J. S. Huxley begins a course of six lectures on Evolution and the Problem of Species, and on Thursday, Jan. 31st, Sir William Bragg gives the first of three lectures on the Early History of X Rays.

ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.—A post-graduate course in orthopædic surgery will be held at this hospital from March 11th to 23rd, with lectures and demonstrations daily. Further particulars may be had from the Secretary of the hospital, 234, Great Portland-street, London, W. 1, or from the Fellowship of Medicine.

ROYAL LONDON OPHTHALMIC HOSPITAL. — The annual dinner of past and present students of this hospital will be held at the Langham Hotel, Portland-place, London, W., on Thursday, Feb. 7th, at 7 for 7.30 o'clock. Mr. Charles Howard Usher will preside, and applications for tickets should be addressed to Sir William Lister, 24, Devonshire-place, W. 1.

HOSPITAL ASSESSMENTS.—Considerable increases have been made in the valuation of hospitals in the area of the North Middlesex Assessment Committee: the Prince of Wales's Hospital, Tottenham, has been raised from £335 to £1650; Hornsey Central from £20 to £440; Wood Green from £15 to £300; Enfield from £12 to £372.

ST. BARTHOLOMEW'S NURSES.—Last week the Lord Mayor of London declared open the new recreation rooms of Queen Mary's Home for the St. Bartholomew's Nurses. There are separate sitting-rooms for nurses and probationers, a lecture-room, a class-room, and the Isla Stewart Memorial Library. Two blocks of the home are already in use, and it is hoped that the southern extension will be ready for occupation late in the present year.

LIVERPOOL JEWISH HOSPITAL.—A house in Alexandra-road, Aigburth, has been purchased for conversion into a Jewish hospital. The building has passed the scrutiny of a committee of 20 medical men.

A "SILVER PAPER" COT.—Viscountess Craigavon, wife of the Prime Minister of Northern Ireland, last week gave this name to a cot in the Ulster Hospital for Children and Women, Belfast. It has been endowed with money derived from the sale of "silver paper."

A SCOTTISH FEVER AND TUBERCULOSIS HOSPITAL.—Major Walter Elliot, M.P., recently opened a new fever and tuberculous hospital at Wester Moffat, Airdrie. The work has cost £36,000.

NAVAL MEDICAL COMPASSIONATE FUND.—At a quarterly meeting of the directors of the Fund, held on Jan. 22nd, Surgeon Vice-Admiral Arthur Gaskell, Medical Director-General of the Navy in the chair, the sum of £100 was distributed among the several applicants.

GLASGOW STUDENTS' COLLECTIONS FOR CHARITIES. The students of Glasgow University on Jan. 19th collected over £15,000 for local charities, and several contributions have still to be added. It is expected that this year's collection will be little short of that of last year's, which amounted to £16,500. In nine years the Glasgow students have raised nearly £100,000 for local charities.

LONDON, MIDLAND, AND SCOTTISH RAILWAY HOSPITAL FUND.—The total receipts of this fund last year were £145,000, of which £40,000 was contributed by the Company and £105,000 by the men. Hospitals received £90,000 and convalescent homes £20,000 ; dental treatment and surgical and optical appliances absorbed £25,000.

RADIUM IN SWEDEN.—Six grammes of radium sulphate, purchased at a cost of £63,000, is the first result of the national gift of the Swedish people to King Gustaf V. on the occasion of his seventieth birthday last year. According to the special wish of the King, this gift fund, which now amounts to more than £280,000, will be used entirely for fighting cancer.

ULSTER MEDICAL SOCIETY.—At a meeting of this Society on Jan. 10th the President, Prof. T. H. Milroy, moved, and Dr. J. S. Morrow seconded, a resolution recording appreciation of the valuable services rendered to the Society by the late Dr. W. L. Storey, who for 35 years took an active interest in all its affairs.—Dr. S. B. Boyd Campbell read a paper on the Treatment of the Sequelæ of Encephalitis Lethargica by Malaria, demonstrating a number of cases to the meeting, and reviewing a series of 50 cases in which this method had been tried. Dr. J. S. Morrow, Dr. A. Gardner Robb, Sir Thomas Houston, Dr. F. Coates, Dr. J. C. Young, Dr. N. B. Graham, Dr. W. Burns, Mr. J. O'Doherty, and the President joined in the discussion which followed.

TORBAY HOSPITAL CONTRIBUTORY SCHEME. — A town's meeting at Torquay has adopted a contributory scheme for the recently opened Torbay Hospital. Contributors will be divided into three classes. Class 1 will have an income-limit of £200 a year for a single person over 16, or a widow or widower without children under that age, who will contribute a penny a week. Class 2 will have an income-limit of £250 for married couples without children under 16, and persons with one dependent under that age, who will contribute twopence per week. Class 3 will have a limit of income of £300 for married couples with a child or children under 16, and persons with more than one dependent under that age, who will contribute threepence weekly. Letters will be required only for non-contributors, who will be expected to pay towards their maintenance at the hospital and for the use of the ambulance.

THE FUTURE OF SURGERY.—In the course of an address delivered in opening the new operating theatres at the Leicester Royal Infirmary on Jan 23rd, Mr. C. J. Bond said that it was quite likely that the principles and practice of surgery would undergo change and development as knowledge grew. For instance, it might be that the all-penetrating beta and gamma rays, with their associated bombarding projectiles from a disintegrating radium atom on its way to become lead, would exercise a more discriminating and lethal effect on growing and multiplying cancer cells than the sharpest knife of the most skilful surgeon. It might be that, instead of incising and draining abscesses, the surgeon of the future would be busy in preventing their formation by the timely supply into the blood stream of antitoxins and other immunity-conferring materials. The surgeon of to-morrow must be a pathologist as well as a surgeon. He must be more and more concerned with the biochemical and physiological principles which underlie the healing of wounds, and normal and disorderly cell growth. In the industrial world to-day there was a danger that the man might be enslaved by the machine. In the same way a too rigid observance of ritual, and a too confined attention to the merely mechanical side of the art of surgery, must not be allowed to limit the surgeon's outlook. He was, or should be, concerned with living forces, not dead.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
MONDAY, Jan. 28th.—8 P.M., ODONTOLOGY. Casual Communications: Mr. A. T. Pitts: Two Compound Composite Odontomata. Dr. J. Kingston Barton: The Prevention of Diseases of the Teeth in Children. Mr. W. Rushton: The Use of Cement Linings in Cavities. Paper: Mr. G. B. Pritchard: Some Notes on the Origin and Prevention of Gingivitis.
FRIDAY, Feb. 1st.—10.30 A.M., OTOLOGY. (Cases at 9.30 A.M.) Demonstration of some graphic records of instability illustrative of cases referred to by Mr. Sydney Scott, by Dr. A. Lowndes Yates. Papers: Mr. Sydney Scott: Vertigo. Mr. A. R. Tweedie: Some Notes on the Rotation Caloric and Galvanic Tests. Cases and specimens will be shown by Mr. E. A. Peters, Mr. M. Vlasto, Mr. Archer Ryland, Mr. W. N. M. Girling, and Mr. Eric Watson-Williams. 5 P.M., LARYNGOLOGY. (Cases at 4 P.M.) Cases and specimens will be shown by Mr. Eric Watson-Williams, Mr. F. J. Cleminson, Mr. Norman Patterson, and others. 8.30 P.M., ANÆSTHETICS. Paper: Dr. R. D. Lawrence: Post-operative Acidosis.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.
MONDAY, Jan. 28th.—8.30 P.M., Discussion on Starvation in Treatment, introduced by Dr. E. I. Spriggs, followed by Sir Thomas Horder.

ROYAL INSTITUTION, 21, Albemarle-street, W.
THURSDAY, Jan. 31st.—5.15. P.M., Sir William Bragg: The Early History of X Rays.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn, W.C. (Hunterian Lectures.)
MONDAY, Jan. 28th.—5 P.M., Prof. Arthur Evans: Developmental and Enterogenous Cysts and Diverticula.
WEDNESDAY.—5 P.M., Prof. G. E. Gask: Treatment of Malignant Diseases by Radium (with demonstration of patients).
FRIDAY, Feb. 1st.—5 P.M., Prof. C. A. Pannett: Local Anæsthesia in the Surgery of the Upper Abdomen.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham, N.
MONDAY, Jan. 28th.—2.30 to 5 P.M.: Medical, Surgical, and Gynæcological Clinics. Operations.
TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin, and Eye Clinics. Operations.
THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.
FRIDAY, Feb. 1st.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, 49, Leicester-square, W.C.
TUESDAY, Jan. 29th.—5 P.M., Dr. W. J. O'Donovan: Exfoliative Dermatitis.
THURSDAY.—5 P.M., Dr. H. Haldin-Davis: Pruritus, Prurigo, Lichenification.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
MONDAY, Jan. 28th, to SATURDAY, Feb. 2nd.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Mon., at 5 P.M., Lecture, Mr. Malcolm Hepburn: Some Apparent Difficulties of General Practitioners in Ophthalmic Work.—HOSPITAL FOR CONSUMPTION, Brompton, S.W. Tues., at 4.30 P.M., Clinical Demonstration by Dr. Batty Shaw.—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Tues., at 4–6 P.M., Lecture: The Injection Treatment of Varicose Veins, followed by a demonstration of the methods and results in over 50 cases by Mr. Rodney Maingot.—WELLCOME MUSEUM OF MEDICAL SCIENCE, 33, Gordon-street, W.C. Wed., at 4 P.M., Demonstration by Dr. R. A. O'Brien on Vaccines and Sera: their Prophylactic and Therapeutic Value in General Practice. The above are free.—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N. Intensive course in Medicine, Surgery, and the Specialties, for two weeks.—BETHLEM ROYAL HOSPITAL, S.E. Tues. and Sat., at 11 A.M., Lecture-demonstrations.—QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, E. Second week of special course. Further particulars from the Secretary.

NATIONAL HOSPITAL, Queen-square, Bloomsbury
MONDAY, Jan. 28th.—12 noon, Dr. Greenfield: Pathology of Nervous System. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Mr. Williamson Noble: Optic Neuritis.
TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Transient Hemiplegias and Similar Cerebral Attacks.
THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Mr. Just: Methods of Testing the Eighth Nerve.
FRIDAY, Feb. 1st.—12 noon, Dr. Purdon Martin: Anatomy and Physiology of Nervous System. 2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educative Methods.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Jan. 31st.—4 P.M., Mr. Lloyd: Some Orthopædic Principles.

ST. MARY'S HOSPITALS POST-GRADUATE LECTURE, Manchester.
FRIDAY, Feb. 1st.—4.30 P.M. (at the Whitworth-street West Branch), Dr. Dougal: The Management of Occipito-posterior Positions.

NATIONAL COUNCIL FOR MENTAL HYGIENE.
WEDNESDAY, Jan. 30th.—5 P.M. (at the Medical Society of London, Chandos-street, W.), Dr. Hugh Crighton-Miller: Dangerous Ages: Youth.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.
FRIDAY, Feb. 1st.—3.30 P.M., Mr. Graham Simpson: Surgical Cases.

Appointments.

ABEL, A. LAWRENCE, M.S. Lond., F.R.C.S. Eng., has been appointed Surgeon to the Cancer Hospital.
BACK, MARJORIE, M.D. Lond., D.P.H. Camb., Assistant Medical Officer of Health for the county of Surrey.
GARLAND, H. S., M.B. Lond., M.R.C.S., House Physician, National Hospital, Queen-square, W.C.
KEITH, F. L., M.D. Aberd., D.P.H., Medical Officer of Health for Deptford.
MILLER, ARTHUR A., D.L.O., M.R.C.S., Assistant Out-patient Registrar to the Central London Ear, Nose and Throat Hospital.
WEBSTER, J. M., M.B., Ch.B. St. And., F.R.C.S. Edin., Surgeon to the Sheffield City Constabulary.
Certifying Surgeons under the Factory and Workshop Acts: BICKNELL, A., M.D. Liverp. (Holylake, Chester); FULLERTON, J. A., M.B., Ch.B. Edin. (Mossley, Lancs.); HAMMERTON, G. H. L., L.R.C.P., L.R.C.S. Edin. (Dewsbury); STEWART, W. P. A., M.B., Ch.B. Glasg. (Kilbride-Bute); and WHITLEY, J. T., M.B., Ch.B. Manch. (Chelmsford, Essex).

Vacancies.

For further information refer to the advertisement columns.

Barnstaple, North Devon Infirmary.—Res. M.O. At rate of £150.
Birkenhead General Hospital.—Hon. Physician.
Birmingham, Little Bromwich, City Hospital for Infectious Diseases.—Fourth Asst. M.O. £300. Also Two Visiting Surgeons. Each £200.
Birmingham Royal Cripples Hospital.—Sen. H.S. £400.
Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. At rate of £120.
Bolton, Townleys Hospital, Farnworth.—Asst. M.O. £400.
Bradford Royal Infirmary.—Two H.S.'s. Each £150.
Cardiff Royal Infirmary.—Ophth. H.S. Also Gynæcological H.S. At rate of £75 and £50 respectively.
Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Res. H.S. At rate of £75.
Chadwick Trustees.—Two Travelling Scholarships. £400 each.
Charing Cross Hospital, W.C.—Asst. Physician.
Coventry and Warwickshire Hospital.—Res. H.S. £125.
Dreadnought Hospital, Greenwich.—Physician to Out-patients.
Durham County Council, Education Department.—Asst. School M.O. £600.
Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. Pathologist.
Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120.
Glasgow, Gartloch Mental Hospital, Gartcosh.—Jun. Asst. M.O. £300.
Glasgow Royal Cancer Hospital.—Medical Officer. £600.
Gloucester County Mental Hospital.—Jun. Asst. M.O. £350.
Great Yarmouth, General Hospital.—H.S. £150.
Hospital for Sick Children, Gt. Ormond-street, W.C.—Cas. O. £400. Also Asthma Research Scholar. £300.
Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Asst. Surgeon.
Ilford Isolation Hospital.—Temporary R.M.O. £350.
Jersey Mental Hospital.—Med. Supt. £650.
Leyton Borough.—Asst. M.O. £600.
London Temperance Hospital, Hampstead-road, N.W.—Med. Reg. 40 guineas.
Maidstone, Kent County Ophthalmic and Aural Hospital.—Ophth. H.S. Also H.S. to Ear, Nose and Throat Dept. Each at rate of £200.
Malayan Medical Service.—Medical Officers. £700 per annum.
Melbourne University, Victoria, Australia.—Chair of Obstetrics. £2000.
Metropolitan Asylums Board.—Bio-chemist at the Board's Anti-toxin Establishment, Sutton, Surrey. £600.
Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Asst. Radiologist.
Oxford, Radcliffe Infirmary and County Hospital.—Hon. Surgeon.
Plymouth, South Devon and East Cornwall Hospital.—Cas. H.S. At rate of £100.
Preston Union.—Jun. Res. M.O At rate of £104.
Princess Louise Kensington Hospital for Children, North Kensington.—Hon. Asst. Surg.
Queen's Hospital for Children, Hackney-road, E.—Asst. Surg.
St. Mary's Hospital for Women and Children, Plaistow, E.—Res. and Asst. Res. M.O.'s. At rate of £175 and £120 respectively.
Salisbury, General Infirmary.—Res. M.O. £150.
Southampton County Borough.—Asst. School Dentist. £150.
Stafford, County Mental Hospital.—Second Asst. M.O. £600.
Swansea County Borough Infectious Diseases Hospital.—Res. M.O. £350.
Warwickshire County Council.—Asst. County M.O.H. £600.
Wellington Hospital, New Zealand.—Orthopædic Specialist. £900.
West Bromwich, Hallam Hospital, Hallam-street.—Ophthalmic Surgeon. £75.
West London Hospital, Hammersmith-road, W.—Hon. Obstetric Registrar.
Willesden General Hospital, Harlesden-road, N.W.—Hon. Ophthalmic Surgeon.
Woolwich and District War Memorial Hospital, Shooters' Hill, S.E.—H.S. At rate of £125.
Worcester County and City Mental Hospital, Powick.—Jun. Asst. M.O. £350.
York, The Retreat.—Jun. M.O. £300.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at New Tredegar (Monmouthshire), Grampound (Cornwall), Drummore (Wigtownshire), Pulborough (Sussex), West Linton (Peeblesshire), Kippen (Stirlingshire), and Waltham Abbey (Essex).

The Home Secretary gives notice of vacancies under the Workmen's Compensation Act, for the Districts of the Abergavenny and Blaenavon, Crickhowell, Monmouth, and Tredegar, Abertillery and Bargoed County Courts, and for the Districts of Llangefni, Holyhead and Menai Bridge County Courts (Circuit No. 29). Applications should reach the Private Secretary, Home Office, not later than Feb. 7th.

Births, Marriages, and Deaths.

BIRTHS.

ALEXANDER.—On Jan. 16th, at Queen-square, Lancaster, the wife of Dr. Alexander, of a son.
ANDERSON.—On Jan. 19th, at Ribblesdale House, Hornsey, the wife of Roy S. Anderson, M.R.C.S., L.R.C.P., of a son.

MARRIAGES.

BRAHAM—HINCKS.—On Jan. 21st, Noel Braham, O.B.E., M.C., F.R.C.S., to Mrs. Ruth Hincks, daughter of the late Ludwig Wiborg, of Brevik, Norway.

DEATHS.

BAKER.—On Jan. 16th, suddenly, at Elmstead, Andover, Hants, Henry Francis Baker, F.R.C.S., aged 83.
BIANCHI.—On Jan. 17th, at Brighton-place, Portobello, Edinburgh, Leo Ferdinando Bianchi, F.R.C.S., F.R.C.P. Edin.
BIRKETT.—On Jan. 19th, at "Merrilyn," Lee-on-the-Solent, Dr. H. J. D. Birkett.
BROOK.—On Jan. 7th, at Biskra, Algeria, Rev. Thomas Brook, B.D., LL.D., M.D., D.P.M., Chaplain to the Forces (retired), aged 58 years.
COLBORNE.—On Jan. 15th, at Hayling Island, the Rev. George Colborne, M.A., Ph.D., M.R.C.S., L.R.C.P., aged 83 years.
HUCKLE.—On Jan. 13th, at Tillington Lodge, Hastings, Arthur Henry Headley Huckle, J.P., of the Middle Temple, Barrister-at-Law, M.R.C.S., L.R.C.P., D.P.H.
SOWDEN.—On Jan. 19th, at St. Giles, Elgin, George Smith Sowden, M.A., M.D., aged 46 years.
SQUIRE.—On Jan. 13th, at Granville Lodge, Westgate-on-Sea, Maurice Frederick Squire, M.D., M.R.C.S., L.R.C.P.
VICKERY.—On Jan. 12th, at Brighton, after a short illness, Alice Vickery, L.R.C.P. Irel., in her 85th year.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

INDEX TO "THE LANCET," VOL. II., 1928.

THE Index and Title-page to Vol. II., 1928, which was completed with the issue of Dec. 29th, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

Notes, Comments, and Abstracts.

THE TRAINING OF THE COMPLEAT CHYRURGION:

THE BACKWARD LOOK AND THE LOOK AROUND.*

BY ARCHIBALD YOUNG, B.Sc., M.B., C.M., F.R.F.P.S. GLASG.,

REGIUS PROFESSOR OF SURGERY, UNIVERSITY OF GLASGOW.

THE training of "the compleat chyrurgion" must be a thorough and comprehensive process, and cannot be accomplished even approximately within the limited number of years that he is an undergraduate. Only if his early training is well founded and securely based may one look with confidence for the larger development and the greater competency that the surgeon must have if he is to be in any real sense "compleat." His training must go on without cessation all through his active life, and he must keep himself *au fait* with every development of his science and of his art. Reading, observation, experiment, discussion with others, young as well as old—and perhaps he will get in many ways a greater inspiration from the former than from the latter—these and other sources of knowledge and of improved technique must be utilised to the full. Two directions of study, two aspects of the surgeon's training, will amply repay cultivation: medical history and travel.

THE BACKWARD LOOK.

We are apt to get into the habit of assuming that most of the achievements of the surgery of to-day are peculiar to this century, half century, or even this last decade; that there was indeed no such thing as surgery, as we now understand it, until almost within the memory of our grandfathers. It is a very salutary corrective to this impression or assumption to glance back for a little upon the history of surgery in the past. It is not its earlier primitiveness, its extremely limited scope and achievement in earlier times, that surprise us, but rather the extraordinary state of development, especially on the technical side, to which it had attained even many centuries ago. As far back as 360 B.C., Hippocrates made use of counter-irritation, used the actual cautery, set fractures, and trepanned the skull. Celsus (A.D. 17) performed lithotomy. He did amputations. He described an operation for cataract. He was probably the first to recommend the ligature of arteries for the arrest of hæmorrhage. He even attempted the radical cure of hernia. Like Hippocrates, he trepanned or trephined the skull. Galen (A.D. 150) developed the art of bandaging, described and used complicated machinery for the treatment of fractures and dislocations, and like Celsus, employed ligatures for the control of hæmorrhage. Paulus Æginata (A.D. 700) performed many operations, such as lithotomy, laryngotomy, tracheotomy, and amputation of the breast. One might multiply evidence of this kind almost indefinitely. Let us trace the history of the development of surgery in one particular department.

The Operation of Trepanning.

Trepanning certainly goes back as far as the time of Hippocrates—that is, over 300 years before the Christian era—but Lucas-Championnière, in his "Les Origines de la Trépanation décompressive," depicts a skull from the Neolithic period, which shows a large smoothly rounded orifice in the left parieto-occipital region, almost certainly the relic of a therapeutic trephining. Had it been done at the present day it could hardly have been bettered; and it must have been done with flint. Victor Horsley, after making a careful investigation of the skulls in the Broca Museum in Paris, in 1887, concluded: "(1) That the operative openings were nearly always over the site of representation of movement on the cerebral cortex; (2) that the patients had probably been suffering from Jacksonian epilepsy; (3) that the operation would gain a certain reputation for the cure of convulsions generally; and (4) that at least some of the operations—e.g., for depressed fracture—would result in cure" (Ballance).

It is clear that Hippocrates trepanned the skull for the purpose of decompression, to relieve inflammation, for the evacuation of pus and blood, and for the extraction of foreign bodies. His writings show also—and this is perhaps the most remarkable fact of all—that he recognised the contralateral distribution of convulsions and paralyses following upon certain head injuries. It is on record, too, that he recommended the use of the trephine for the treatment of blindness not due apparently to any obvious disease of the eye. This is surely the very earliest known recognition of the value of decompressive trephining for the relief of optic neuritis. Celsus advocated trephining for the evacuation of blood poured out between the dura and bone, and forming a clot, even where the bone was not obviously broken. From these early times and on through the centuries operations on the skull continued to be practised, and we find in the writings of Roger of Salern (A.D. 1170), Walter of Agilon (middle of thirteenth century), Ambrose Paré (1560), Andreas a Cruce (1573), Fabricius Hildanus (1560–1634), references to trephining or trepanning for fracture of the skull, for the relief of pressure by blood or pus, and for the treatment of "dolor capitis." Descriptions are given as to how a sufficiently large opening may be made by joining up adjacent trephine holes, to allow of the removal of the intervening bone. There are in some of the works—e.g., those of Andreas a Cruce and Peter Paaw—numerous illustrations of such operations and of the instruments employed. It is of interest to compare the latter with some of our present-day instruments; the resemblances are more remarkable than are the differences. Some of the instruments credited to Hippocrates—both trepans and trephines—are furnished with devices to prevent them penetrating too deeply. These devices are in some cases bars or rings; some of the instruments are bevelled from below upward; some of the trephines have metal collars not unlike the collar guard of the trephines of to-day.

There are other simpler instruments figured in the same works which bear a very close resemblance to many in common use at the present time. The words of the Preacher must surely come back to our minds, as we survey the armamentarium of Hippocrates, and compare it with our own: "The thing that hath been, it is that which shall be; and that which is done is that which shall be done and there is no new thing under the sun. Is there anything whereof it may be said—See, this is new? It hath been already of old time, which was before us."

Percival Pott (1713–1788), Petit (1674–1750), John Hunter (1728–1793), Larrey (1766–1842) and others, with varying courage and with a gradually advancing degree of clinical exactitude, carried out operations on the skull for injuries occurring both in civil and in military practice and began to correlate clinical observation with operative and post-mortem findings. Larrey, for example, observed the effects of injury to various regions of the brain, and noted some facts of importance in cerebral localisation such as loss of memory, aphasia, contralateral palsy, the homolateral paresis of cerebellar lesions, the respiratory failure of cerebellar lesions, and the connexion of cerebellar abscess with otitic disease. Petit's instruments are very similar to some that have been in common use in our own time. His trephine was cone-shaped, and had outside serration. His "trépan exfoliatif" was very like the carpenter's bit of the present day. In the writings of Hunter there are accounts of operations by him upon the skull, the brain and the meninges, and his records are good examples of his well-known carefulness in observation and in reporting. Trepanning, however, passed through many vicissitudes and its repute varied widely from time to time. For example, so recently as 1840 Pirrie said: "These fractures, and the numerous inventions of instruments for cutting the skull, are sad monuments of the Surgery of past ages." That the lay mind, however, even quite early, was not averse from seeing good in the operation, is attested by many examples, and there is the historic instance of Philip Count of Nassau, who was thrown from his horse while riding and sustained a fracture of the skull. Having ultimately made a good recovery, he gave his surgeon the following testimonial: "I, the underwritten Philip Count of Nassau, hereby declare and testify that Mr. Henry Chadborn did trepan me in the skull 27 times, and after that did cure me well and soundly." Astley Cooper (1768–1841), though he practised trephining in selected cases, seems to have discouraged it, except in compound fractures of the skull, though he mentions one case of cure of Jacksonian epilepsy by operation.

The rule of practice established by Pott was to the effect "that, in every case of fracture of the skull, with depression the skull should be perforated, and the depressed fragment of bone either raised to its proper level or entirely removed." This rule came to be set aside, it appears, mainly by reason of the authority of Abernethy who, about the year 1811 A.D., set forth as his opinion that trephining might often be dispensed with, even in fractures of the skull where depression of bone was definitely known to be present. In support of his view Abernethy related five cases of fracture of the skull with depression, which he had under his care at St. Bartholomew's Hospital within 12 months, and which terminated favourably though no operation was performed. Thereafter, according to Francis Adams, in "The Genuine Works of Hippocrates," "it became the established rule of practice in British surgery never to interfere in cases

* Abstracted from a presidential address delivered to the Glasgow University Medico-Chirurgical Society.

acture of the skull unless with the view of removing rgent symptoms." This reactionary teaching seems to ave held the field for close on 30 years, and in accomtishing its overthrow, and bringing back surgical opinion o the teaching of Pott, Francis Adams ascribes a notable lace to what he terms "the elaborate and trustworthy atistics, published in 1844 A.D., by Dr. Lawrie of Glasgow" ater Regius professor of surgery—the immediate preecessor of Lister). These statistics were compiled from ie records of the Glasgow Infirmary. Lawrie's conusion was as follows: "From what we have said, it will ppear that we coincide with those who, in using the 'ephine, in cases of compound fracture of the skull, look iore to the state of the bone than to the general symtoms, and who employ it more as a preventive of nflammation, and its consequences, than as a cure for rgent symptoms, the immediate result of the accident." his is surely a very unique and remarkable example of the alue and effect of carefully compiled statistics and careful eduction therefrom.

THE "LOOK AROUND."

It has long been an accepted fact that travel is a valuable djunct in any liberal system of education. No nation robably more than the Scots have recognised the educative alue of travel. Even in mediæval times Scotsmen travelled ar abroad, in France, Italy, and the low countries. Scots udents were found at many continental colleges and niversities, and not a few Scotsmen even held professorial hairs abroad. In addition to those who travelled thus or purely educative purposes, many spent time and fortune n the Spanish Wars and in the wars in the Low Countries, eturning later on to play their several parts at home. ven in comparatively recent times, a period of travel broad has been generally regarded as an important factor n the completion of a good general education, so that uch a term as the "travel year" or "Wanderjahr" has ound its way into accepted literature and even into classical ictionaries. If desirable as an adjunct to any liberal eneral education, it is all the more to be recommended s a valuable agent in the training of the surgeon.

The special benefits to be expected from properly directed ravel are many. Other people, other methods of working, ther points of view encountered in the course of travel ust suggest to the receptive imagination new aspects f truth, which, after all, is many sided. It is well to ealise that truth is not bound up in a closed packet, possessed y any one school of thought, but is the heritage of all, nd it is bound to be appreciated in different ways by iffering schools of thought. It follows that the practical pplications of truth have many different possibilities, nd it may be the lot, or the luck, of one school to perceive direction of advance that is obscured to other schools. he surgeon who visits other schools, with an open mind, an hardly fail to pick up ideas that may fructify in many seful ways. In his own school, and working constantly mong others of his school—competent though they be—he surgeon is apt to become wedded to stereotyped methods nd locally accepted dogma. Let him travel, visit other chools, whether at home or abroad, and witness the work f others. He is set a-thinking, and his outlook is inevitably roadened. So must his technique and his practice profit y what he sees, whether or not he be led to adopt the new nd to discard or modify the old.

There is little doubt that one of the most attractive eatures of a travel tour, whether at home or abroad, is he opportunity it affords of seeing some of the famous ien whose names are known to us by their notable researches r writings. It will not always happen that contact with man and his work will confirm a preconceived estimate ased on the study of his writings, but even disillusionment s a definite gain, for one knows thenceforward what value o place upon further publications from the same source. t has, however, seldom been my experience to encounter uch disillusionment. In nearly every case the man whom have judged on the basis of his published works to be a reat surgeon has proved to be greater than his writings, nd it has been, in consequence, a satisfaction and an nspiration to see him at work in his own clinic or laboratory. chools achieve fame, centres of learning acquire distinction, argely in virtue of the great names upon the rolls of their rofessoriate or teaching staff. It is almost always the nan who counts, and the traditions of a school are built p on the records of work done by famous members of the taff, whose memory and whose standing are held in high onour by alumni and adherents. The great surgeon whom lone you desire to meet upon your travels will be a man ompounded of all sorts of qualities, amongst which mere nanual dexterity, and what might be called brilliancy in perating, may take but a secondary place. But no urgeon can be truly great unless his practice be humane, nd unless he be as honest with himself as with his fellows, laiming for no procedure, for no operation—however rilliant or however personal to himself and to his reputation —one jot of credit more than its results indisputably warrant.

At what stage in his career should the surgeon fare forth to see the world? Should he set out immediately his Alma Mater has conferred on him his graduate degree? Or should his "Wanderjahr" come later on, when a further spell of post-graduate study has already added substantially to his groundwork of knowledge? This is a question that is not easy to answer. The decision will depend very much on the manner in which he proposes to plan his travel. If he intends to go to one or two places only, and to settle down there for a definite period of continuous study, under the guidance of a man who is an acknowledged authority in the special line of his projected study, then I see no reason for delay. But I doubt if, at this early period of his career, the young surgeon will profit much by a mere tour of travel in which he visits many different clinics, spending, it may be, but a day or two in each. The fresh graduate is unlikely yet to have the mental balance which would enable him to profit by such a haphazard collection of observations as he may thus acquire. For the mature man, well grounded in his science and well versed in its modern developments, who has already acquired for himself a substantial experience and who is now fitted to assess values, it is a very different thing. For him it will be, in the years that follow, a means of constant refreshment to visit other schools and clinics, and will serve him as a recurring corrective in his practice. To the immature man, the effect of such a tour may even be harmful, in that it may lead him to form erroneous opinions, based on insufficient data and wrongly assessed impressions. Let it not be supposed that travel as a means of surgical training must be necessarily or exclusively travel abroad. Much may be gained by visits to schools and clinics in our own country, and I have often thought that it would be a good thing if we had some regular and regularised interchange of students and of teachers between the various schools at home.

From his travel tour the surgeon will return, I hope, with much valuable information, and many new ideas, to help him in his further development. But I am confident that you, if you travel, will have the same experience as I have had; the same feeling of deep satisfaction that has been mine in coming again amongst our own people. With each recurring visit I pay to other clinics I come back to my own with a deep sense of satisfaction. There *are* things—and they are not few—which we do better here than elsewhere; there *are* many aspects and departments of surgery which are certainly as far advanced, as well developed, here as in other schools. We are heirs to great traditions; let us see that these great traditions remain unsullied.

PUBLIC HEALTH IN NORTHERN RHODESIA.

THE territory known as the Protectorate of Northern Rhodesia lies between longitudes 22° E. 35′ E., and between latitudes 8° 15′ S. and 18° S. It is bounded on the west by Angola, on the north-west by the Belgian Congo, on the north-east by Tanganyika Territory, on the east by the Nyasaland Protectorate and Portuguese East Africa, and on the south by Southern Rhodesia and the mandated territory of South-West Africa—comprising in all an area that is computed to be about 278,950 square miles. The River Zambesi forms the greater part of the southern boundary; its two main northern tributaries are the rivers Kafue and Luangwa. With the exception of these river valleys, the territory consists of a table-land varying from 3000 to 4000 feet in height, though in the north-eastern portion, and especially in the vicinity of Lake Tanganyika the altitude is greater. At the present time statistics are available of 70 different tribes resident in the Territory, and there are said to be 38 distinct native languages in use. Previous to 1889 the whole territory had been vaguely included in the Charter granted to the British South Africa Company, but in that year the Barotseland (North-Western Rhodesia) Order in Council placed the administration of the western portion of the country by the company on a firm basis; and this was closely followed by the North-Eastern Rhodesia Order in Council of 1900 with similar effect. The two territories were amalgamated in 1911 under the designation of Northern Rhodesia, and the administration of the company continued until 1924, when, in terms of a settlement arrived at between the Crown and the Company, the administration of the Territory was assumed by the Crown, and the first Governor (Sir H. J. Stanley) was appointed on April 1st of the same year. He was succeeded in August, 1927, by Sir J. Crawford Maxwell.

Climate.

There are considerable climatic differences between various parts of the country. The Zambesi, the Luangwa, and the Kafue valleys experience a much greater humidity and a more trying heat than do the plateaux above 3500

or 4000 ft. The hottest months are October and November, before the rains break, when the mean maximum is about 97° F. in the Zambesi valley stations and 85° at plateau stations. The mean maximum for the eight months of the hot season (September to April) is approximately 90·3° with a mean minimum of 64·5° while the corresponding figures for the four months of the cold season (May to August) are 78·7° and 46·6° The highest temperature recorded in the Territory was 116° at the Barotse National School in October, and the lowest was 22° at Sesheke in July.

The rainy season usually commences in November and lasts until April, after which month rain is only rarely experienced, and then in negligible quantities. The rainfall recorded at Livingstone was 19·17 in., at Broken Hill 31·42 in., at Fort Jameston 41·82 in., and at Abercorn 44·17 in. In the western districts 55·51 in. were recorded at Mwinilurga and 46·36 in. at Mongu. Minor earth tremors were felt at various places in the Territory.

Vital Statistics.

In the latest official report on the affairs of the Protectorate, prepared by Mr. G. A. S. Northcote, Chief Secretary, the native population is estimated at 1,237,486. There is, it is stated, no system of birth or death registration possible at present and consequently no figures are available from which vital statistics may be obtained. Infantile mortality is known to be high and has been estimated to be between 40 per cent. and 50 per cent. of children born. The European population in 1927 was 7275, and their general health was good. The death-rate per 1000 was returned at 9·89 (as against 11·1 in 1926, and 13·7 in 1927). 144 children were born, which represents a crude birth-rate of 20 per 1000 as compared with 25·4 per 1000 in 1926.

Hospitals.

The Government maintains European hospitals at Livingstone, Lusaka, Broken Hill, Fort Jameson, and Kasama. Native hospitals are maintained at these places, and also at Mazabuka, Solwezi, Ndola, and Fort Rosebery. In addition, many mission doctors, hospitals, and dispensaries receive annual subsidies from the Government for medical work in native areas. During the year, 923 Europeans and 7288 natives were admitted to hospital and there were 27 and 418 deaths respectively among them. No complete records as to the number of patients treated at out-stations are available for either the European or the native population, though it is estimated that the latter are about 5000, many of whom were treated for trivial complaints.

Infectious Diseases.

One European and 22 native cases of *sleeping sickness* came under treatment, eight of the latter proving fatal. The only epidemic manifestation of the disease was on the Mwangazi River in the Fort Jameson sub-district. Isolated cases of what is presumed to be sleeping sickness have been reported from various parts of the Luangwa Valley, but the disease is not now prevalent there.

The following table gives the number of persons admitted to hospital suffering from *malaria* and *blackwater fever* with mortality statistics in each case, figures being also given for 1925 and 1926 :—

Year.	European population.	Malaria.		Blackwater fever.	
		Cases.	Deaths.	Cases.	Deaths.
1927 ..	7275 ..	272	6 ..	20	5
1926 ..	5581 ..	262	1 ..	21	7
1925 ..	4624 ..	211	6 ..	13	7

Influenza has been present over the whole Territory, but the incidence shows a decrease on previous years. The results of the treatment of yaws with bismuth and sodium tartrate continue to be satisfactory; this disease is chiefly prevalent in the Kasempa, Kafue, and Luapula areas.

Native Department statistics show that there are 5218 *lepers* in the Territory, of whom 3816 have been notified to the medical officers. No statistics are available for mortality. A system of voluntary segregation in coöperation with the various missionary societies will shortly be commenced and gradually developed in combination with the establishment of treatment centres for early cases.

Outbreaks of *small-pox*, *chicken-pox*, and *Kaffir-pox* occurred in many parts of the Territory, but were for the most part localised. The mortality-rate was low. 177,290 persons were vaccinated, and, as far as can be ascertained, the results were successful in about 80 per cent. of cases.

Ankylostomiasis is widely distributed amongst the native population. It is impossible to state with any accuracy to what extent bilharziasis is present. Hospital statistics show an infection-rate of about 0·5 per cent. of those examined. It is hoped that in time circumstances will permit of a more comprehensive survey of this and other diseases, and will facilitate the institution of intensive treatment.

(*Continued at foot of next column.*)

THE KING'S ILLNESS.

OFFICIAL BULLETINS.

(*Continued from p. 166.*)

THE following is the text of the official bulletins which have been issued during the past week and signed by Sir Stanley Hewett and Lord Dawson of Penn :—

THURSDAY, JAN. 17TH. 11.30 A.M.

The King has had a good night and progress, though slow, is satisfactory. The next bulletin will be issued on Friday evening. (Signed also by Sir Hugh Rigby.)

FRIDAY, JAN. 18TH. 8.15 P.M.

The King has had a quiet day. There is no change to report in His Majesty's condition. The next bulletin will be issued to-morrow night.

SATURDAY, JAN. 19TH. 8.30 P.M.

The King continues to make slow progress. The amount of nourishment taken in now satisfactory and the general strength is improving.

TUESDAY, JAN. 22ND. 12 NOON.

The King has had a quiet night. The temperature has now remained normal for many days, and the condition of the pulse satisfactory. The empyema wound is small and steadily healing. With a returning appetite the amount of nourishment is adequate and includes solid food. Although the general strength shows improvement, there is not as yet any appreciable increase in weight. We feel the time is approaching when His Majesty's removal to sea air will be advantageous. (Signed also by Sir Hugh Rigby, Sir Farquhar Buzzard, and Sir Humphry Rolleston.)

(*Continued from previous column.*)

There is no indication of the distribution or extent of *tuberculosis*. That the degree of infection is low is indicated by native hospital and out-patient returns and by the medical examination of large numbers of natives for various purposes.

The continued activity in mining operations in the Territory has provided Northern Rhodesia natives with a labour market comparatively close to their homes, and, generally speaking, the response has been very satisfactory. Northern Rhodesia mines offer wages and conditions of housing, feeding, and general attention which compare favourably with the extra territorial labour centres which compete for the Territory's labour.

"OUR TOUNIS COLLEGE."

AN anthology[1] of verse, compiled from the pages of the *Student* by David B. Keir and Walter P. Kennedy, has been issued by the Students' Representative Council of the University of Edinburgh as part of a considered effort to foster the interest in the history and tradition of the University which has become apparent in the post-war renaissance. It consists of over 300 poems which have appeared in the *Student* during the last 40 years, with a few more from other, and earlier, sources. It contains fare to suit all tastes—the gay, the grave; the plaintive and the boisterous; love songs and drinking songs; and excellent fooling; all are here. For the most part the verses reach a high level and possess intrinsic merits which raise them much above the standard of the ordinary college magazine. And although we are told that the volume has been primarily prepared for students and alumni of Edinburgh, we believe it will appeal to a wider public.

PLASMOCHIN IN MALARIA AND BLACKWATER FEVER: A CORRECTION.

IN summarising last week (p. 166) the important work of Dr. Drenowsky on the treatment of malaria by plasmochin in a Bulgarian country practice, the safe dose of this drug was stated not to exceed 0·01 g. per kg. of body-weight. This should have read 0·01 g. per 10 kg. of body-weight, which works out at about gr. 1 (not grs. 10) for a 10-stone man. As the larger dose may easily produce serious results we desire to call immediate attention to the correction.

Arris and Gale Lecture

ON

LYSOZYME.

A BACTERIOLYTIC FERMENT FOUND NORMALLY IN TISSUES AND SECRETIONS.

Delivered before the Royal College of Surgeons of England

BY ALEXANDER FLEMING, F.R.C.S. ENG.,

DIRECTOR OF THE DEPARTMENT OF SYSTEMATIC BACTERIOLOGY, ST. MARY'S HOSPITAL; PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF LONDON.

LYSOZYME is a word I use to denote a ferment-like substance which has the power of killing and dissolving bacteria, and which is widely distributed throughout the body. It is found in most of the secretions and all the tissues of man, and is present in the tissues of other animals and in some vegetables. The bacteriolytic action of lysozyme is not manifest on all bacteria equally. Although it can be shown to have some destructive effect on many pathogenic bacteria, its extraordinary bacteriolytic effect is most easily shown on non-pathogenic bacteria, although even among these there are great differences in sensitiveness. I succeeded in isolating a coccus which is remarkably sensitive to the action of lysozyme, and I have used it largely in investigating the properties of the ferment. Because it is easily dissolved I have called this microbe *Micrococcus lysodeikticus*. When the concentration of lysozyme is great, as in tears or egg-white, solution of this coccus is extremely rapid, so that within 30 seconds at body temperature the large, deeply staining cocci are changed to minute irregular specks of stainable material.

If a suspension of the test coccus be made in normal saline solution so that there is a very definite opacity (say, 5000 million cocci per c.cm.), and to 1 c.cm. of this be added 10 c.mm. of tears (if the tube be kept at 37° C., or better still at 45° to 50° C.), the cocci will be found in a few moments to have undergone complete solution, so that the turbidity will have disappeared and the fluid will be perfectly clear. Tears have the same effect on many fæcal streptococci, but it may take an hour or so to complete the action. Such a rapid and powerful bacteriolytic effect cannot be shown with any other type of antibacterial agency in the body. A very striking demonstration of the rapidity of solution of the cocci by material rich in lysozyme is afforded by taking a thickly grown plate culture of *M. lysodeikticus*, placing on it drops of tears, egg-white and normal saline, and then tilting the plate so that the drops run down over the surface of the growth in separate streaks. After about one minute the thick opaque growth of the coccus will have become transparent where the tears and egg-white have run down, but unaltered where the saline has flowed.

The fact that lysozyme acts as well on dead bacteria as an old culture is in striking contrast to the action of a bacteriophage, which only shows a lytic effect on young, rapidly growing cultures.

The lytic substance is rapidly diffusible through a medium such as the ordinary agar which is used as culture for bacteria.

This can be shown by taking a culture plate of nutrient agar and punching out of the centre a small piece of the medium—e.g., 6 mm. in diameter. Ten c.mm. of tears, egg-white or other lysozyme-containing material, or a small piece of tissue, such as cartilage or liver, is placed in this cavity, and is then covered over with melted agar. When this has solidified, fresh agar is poured over the whole surface of the plate, and then it is thickly planted with *M. lysodeikticus* and placed in the incubator. Next day there will be a thick growth of the coccus all over the plate except over the embedded tissue or secretion, and for a distance up to about 1 cm. around.

Thus, within 24 hours, there has diffused through the medium for a distance of perhaps 1 cm. sufficient lysozyme to prevent the growth of the test coccus. If the plate is further incubated for a week it will be found that diffusion progresses further, so that for a distance of another centimetre or more from the embedded material, the thick opaque growth which was first evident has become transparent and almost invisible from solution of the bacteria.

Occurrence of Lysozyme in the Human Body.

A great variety of tissues and secretions and excretions have been tested with *M. lysodeikticus* and other organisms to see whether they contain this lytic principle. *M. lysodeikticus* is of especial value because it detects smaller quantities of the lytic substance than less sensitive organisms. The lytic principle is present in all the human tissues examined and in most of the secretions, except normal urine, sweat, and cerebro-spinal fluid. The concentration however, varies greatly, as will be seen from Table I.

TABLE I.—*Showing the Relative Lysozyme Content of Tissues and Body Fluids.*

Material examined.	H.D.	Material examined.	H.D.
Synovial fluid ..	1 in 80	Liver	1 in 400
Blood serum ..	„ 80	Tonsil	„ 400
Pleural effusion (clear)	„ 80	Kidney	„ 100
Ascitic fluid ..	„ 50	Intestine ..	„ 500
Ovarian cyst fluid	„ 10	Stomach ..	„ 1000
Fluid from parotid cyst ..	„ 100	Meninges ..	„ 400 (*b*)
Semen	„ 20 (*a*)	Skin	„ 100 (*c*)
		Cartilage ..	„ 1300 (*d*)

H.D. = Highest dilution giving complete lysis of *M. lysodeikticus* in one hour at 45° C.

(*a*) Gave only partial lysis after three hours; (*b*) almost complete; (*c*) incomplete lysis; (*d*) in five minutes.

Of all the tissues cartilage had the strongest concentration, and an extract of cartilage corresponding to 1 part in 1300 parts of normal saline was capable of causing complete lysis of the test cocci in five minutes. On the other hand, the lytic action of brain tissue was so weak that when this was embedded in an agar plate, the surface of which was planted with *M. lysodeikticus*, the area of inhibition of growth was very small or might be absent if there were a thick layer of medium over the embedded tissue.

A number of different fluids from the same individual were tested together to ascertain their lysozyme content (Table II.).

TABLE II.—*Lysozyme Concentration in Fluids from the same Individual.*

Fluid examined.	H.D.	Fluid examined.	H.D.
Blood serum ..	1 in 270	Sputum	1 in 13,500
Tears	„ 40,000	Saliva	„ 300
Nasal mucus ..	„ 13,500		

H.D. = Highest dilution giving complete lysis of the test cocci in one hour at 45° C.

The great concentration of lysozyme in tears is very striking. The tears were secreted within a few seconds of the application of the stimulus, so it is clear that some cells in the lacrymal gland are capable of elaborating lysozyme very rapidly in high concentration or of effecting an enormous concentration of the lysozyme which they might obtain from the blood fluids.

Lysozyme exists also in very considerable concentration in leucocytes. This can be shown by placing two glass rings on a slide, filling one of them with blood, and incubating for one hour to allow of the emigration of the leucocytes on to the surface of the slide. The clot is now thrown off and the leucocytes which are adherent to the surface of the slide are washed from red corpuscles and serum, after which both cells are filled with a strong suspension

of *M. lysodeikticus*. After one hour's further incubation the cocci in the cell which had a carpet of leucocytes have all been dissolved, whereas in the control cell without leucocytes there is no solution of the cocci. In another experiment pus was shaken up with an equal volume of normal salt solution and a little ether as an antiseptic (ether was known not to interfere with the lysozyme). This was allowed to extract overnight, and then the fluid was titrated for lysozyme, when it was found that dilution of 1 in 2000 of this fluid was capable of completely dissolving a turbid suspension of the test coccus in 18 hours. It is clear, therefore, from both of these experiments that leucocytes contain lysozyme in high concentration. Ridley has estimated that the concentration is at least equal to that in tears.

The organs and secretions of some of the lower animals have been tested for lysozyme content. It was found that the lysozyme content in the rabbit and the guinea-pig was very much less than in man. The tissues of the dog stood midway between. The lysozyme concentration is greatest in hen's egg-white, and we have found that a dilution as low as 1 in 60,000,000 has some lytic effect on the test coccus. The yolk had no lytic action. There seems to be considerable differences in the lysozyme content of different birds, as is shown in the following experiment.

The same quantity of egg-white of four different species was embedded in an agar plate and *M. lysodeikticus* was planted thickly over the surface. After incubation there was a considerable difference between the areas of inhibition of growth over the different varieties of egg-white. The actual figures obtained were :—

	Diameter of area of inhibition.
Hen's egg-white	24 mm.
Moorhen's „	11 mm.
Thrush's „	16 mm.
Wagtail's	16 mm.

The tissues of a fish (pike) were found to contain much lysozyme, and its cartilage seemed to be quite as potent as that of man. The eggs of this fish were also found to be very powerful.

The tears of the rabbit, horse, sheep, and turkey were all 30 or more times less potent than those of man on *M. lysodeikticus*.

Among the common garden vegetables tested, the turnip showed the greatest content in lysozyme, but even this was very weak when compared with human tissues.

Action of Lysozyme on Different Bacteria.

While, for experimental purposes, *M. lysodeikticus* was usually selected as the most sensitive of the bacteria, at the same time observations were made on other microbes. Of a series of 104 strains of bacteria derived from the air of the laboratory, 75 per cent. were dissolved, more or less readily, by a 1 in 100 dilution of sputum, and 28 per cent. were completely dissolved in one hour.

With bacteria isolated from the human body very variable results were obtained. That this must be so will be obvious when we have dealt with the problem of resistant microbes. Of all the common organisms inhabiting the human body, it is probable that the group showing the least lysis is the *B. coli* group, whereas the most susceptible are the intestinal streptococci. In one experiment 15 strains of intestinal streptococci were placed in contact with undiluted synovial fluid for 8 hours at 45° C., with the result that 12 were completely, and 3 partially, dissolved. Even when tears were diluted 1000 times they still showed some lytic action on a large proportion of the intestinal streptococci. Even though no actual lytic action might be visible when lysozyme-containing fluid was allowed to act on such microbes as *B. coli* or *B. typhosus*, it exerted a bactericidal or inhibitory power on these bacteria. This can be seen in the following experiment.

Equal volumes of dilutions of tears and a suspension of *B. coli* were mixed and incubated for 1 hour when 10 c.mm. of the mixtures were plated, with the result shown in Table III.

TABLE III.

—	Dilution of tears.							Control no tear
	1/2	1/4	1/8	1/16	1/32	1/64	1/128	
Colonies of *B. coli*..	13	13	21	26	30	42	60	182

The various fluids tested did not always bear the same ratio to each other in their lytic power on the different microbes isolated from the human body. Tears, which were by far the most powerful toward *M. lysodeikticus*, were less lytic than sputum or synovial fluid to some other cocci. This may well have some bearing on the immunity of certain tissues to certain infections.

The Nature of Lysozyme.

When a protein precipitant such as trichloracetic acid, alcohol, or acetone is added to egg-white or other lysozyme-containing fluid, the whole of the lysozyme is carried down with the proteid precipitate. Wolff has been able to separate the lysozyme from the protein by precipitation with colloidal iron hydroxide and by further purification by evaporation at low temperature, dialysis, and repeated precipitation with acetone he has succeeded in isolating the whole of the lysozyme from egg-white, protein-free. The purified lysozyme was an amorphous, light-yellow substance, easily soluble in water. The amount obtained from 1 c.cm. of egg-white was 0·1 mg., or very nearly 3 mg., to a good-sized hen's egg.

Effect of Reaction of the Medium.—Lysozyme action only takes place when the medium is approximately neutral. When any appreciable quantity of acid or alkali is present the reaction is delayed or abolished. Thus it is delayed when the medium contains as little as 1/8000 normal acid or 1/24,000 normal alkali, and there is complete inhibition when the fluid contains 1/800 normal alkali.

Effect of Heat.—If a lysozyme-containing material such as egg-white, sputum, saliva, or a tissue extract is heated to 75° C. for half an hour, the bacteriolytic action is completely abolished. In tears, which contain very little protein, this amount of heat does not completely destroy the lysozyme, though it enormously reduces it. For complete destruction it is necessary to boil the fluid for a few minutes. Wolff has also shown that it is necessary to boil purified lysozyme for a short time to effect complete destruction.

Filterability of Lysozyme.—If small quantities of lysozyme-containing material are filtered through a porcelain filter the filtrate will contain none of the lytic substance. When larger quantities are filtered the first portion of the filtrate contains no lysozyme, but later the ferment will come through in full strength.

Egg-white, diluted 1 in 50, was filtered through a Berkefeld filter, and each 10 c.cm. of the filtrate was collected separately and tested for lysozyme. There was no lytic power in the first 50 c.cm. to come through, but after 70 c.cm. had been filtered the lysozyme came through to full strength.

Effect of Chemicals on Lysozyme.—The salt content of the fluid is important. Lysis was most rapid when the salt content was about 0·5 per cent. There was marked inhibition in a concentration of 2 per cent., and in 5 per cent. salt solution the lytic action was practically abolished. Fluids such as alcohol and acetone precipitate the lysozyme but do not destroy it, and egg-white has been found to retain its activity after remaining in these fluids for one year. Dr. Allison has investigated the action of certain antiseptics in common use on the bacteriolytic action of secretions. This was done by making up serial

lutions of the antiseptic in normal salt solution d adding to each of these dilutions known volumes lysozyme-containing material and the test coccus, ving one tube without antiseptic as a control. ble IV. indicates the results obtained, and a third lumn has been added for comparison, giving the ncentrations of the antiseptics which are capable inhibiting the growth of bacteria such as staphylocci in blood.

TABLE IV.

Antiseptic.	Concentration inhibiting bacteriolytic action of tears.	Concentration inhibiting growth of staphylococci in blood.
Eusol..	1 in 128	1 in 2
Chloramine T. ..	„ 32,000	„ 320
Iodine	„ 64,000	„ 400
Carbolic acid ..	„ 80	„ 320
Flavine	„ 30,000	„ 30,000

It will be seen from this table that, especially th the halogen group of antiseptics, the anticterial element of the tears (and incidentally of her secretions and tissues) is much more susceptible the antiseptic than is a common pathogenic cterium such as the staphylococcus.

Production of Resistant Strains.

If some lysozyme-containing material be embedded a culture plate and the surface thickly planted th a sensitive microbe, there will appear, after olonged incubation, in the area where at first there as complete inhibition, a certain number of colonies an organism morphologically and culturally identical th the original microbe. Subcultures are more sistant than was the original to the lytic action of e secretions, and not only are they more resistant the particular tissue or secretion in contact with nich they are grown, but they are more resistant all tissues and secretions. Thus a colony which s been grown in the neighbourhood of human ars will have acquired resistance to the lytic action the tears and, at the same time, to the lytic action other human tissues and secretions, egg-white birds and fishes, and vegetable material such as rnip.

The non-specificity of the resistance acquired in this y can readily be shown by taking an agar plate, cutting t a strip of agar across the middle, filling it with melted ar containing some lysozyme-containing material, and en streaking across the plate, at right angles to the ibedded material, bacteria from non-resistant strains of e test coccus and strains which have been made resistant exposure to various tissues or secretions. Whereas the owth of the non-resistant strains stops some distance ay from the embedded material, growth of resistant ains takes place close up to it. The same sort of result obtained whatever material is embedded and whatever the substance to which the strains have been made sistant.

When a microbe has acquired resistance to lysozyme this way it maintains its resistance for some conderable time, and the resistance has been found diminished after the growth has been subcultured out every two or three weeks for nine months. Table V. shows the gradual increase in the resistance lysozyme which can be induced in an organism by owing in gradually increasing concentrations of a sozyme-containing material such as egg-white. It ll be seen from the table that after 91 weeks' journ in egg-white *M. lysodeikticus*, which was iginally soluble in 1 in 64,000 dilution of the eggnite (in three hours), became so resistant that it as only dissolved completely by a 1 in 800 dilution. ith the streptococcus also the dilution of eggnite which caused complete solution in three hours as altered after 67 weeks from 1 in 800 to less an 1 in 5. It has also been shown that these strains nich have been made more resistant to egg-white e more resistant to the bactericidal power of human ood and to intracellular digestion by human ucocytes.

These experiments, then, seem to indicate a method whereby a non-pathogenic or only slightly pathogenic microbe may increase its virulence. This is supported by the work of my colleague Dr. Ridley who, by exposing staphylococci to lysozyme contained in

tears and cultivating the survivors, has been able to show that these survivors are capable of causing keratitis in a rabbit when injected intracorneally, whereas the original culture was incapable of doing this.

"Absorption" of Lysozyme by Sensitive Bacteria.

The bactericidal substances which exist in blood serum for microbes such as the typhoid bacillus or the cholera vibrio effect a union with the bacteria, so that when the bacteria are removed by centrifugalisation from a serum-bacteria mixture the whole of the bactericidal substances are removed also. Experiments of this kind were done to see whether lysozyme behaved in the same way. The result of these experiments was very surprising; instead of the lysozyme being absorbed by the bacteria and so rendered inactive, its bacteriolytic power was actually increased after the solution of large numbers of microbes.

TABLE VI.—*Showing the Increase of Lytic Power of Tears after Solution of Varying Quantities of* M. Lysodeikticus.

Cocci which had been dissolved by tears.	Amount of lysis observed in dilutions as under of the tears.						
	1/5,000.	1/10,000.	1/20,000.	1/40,000.	1/80,000.	1/160,000.	1/320,000.
0 (control)	+	ac	±	0	0	0	0
0 „	+	ac	±	0	0	0	0
30*	+	ac	±	tr.	0	0	0
300*	+	+	ac	ac	0	0	0
3,000*	+	+	+	ac	±	0	0
30,000*	+	+	+	ac	±	tr.	0

* million per c.cm. tr. = trace.

To measured quantities of tears diluted 1 in 100, graded quantities of *M. lysodeikticus* were added, and the mixtures were incubated at 50° C. for 15 minutes, when lysis of the cocci was complete. The fluids were then titrated for lytic power and compared

with similar volumes of the tear dilution which had not been in contact with the cocci. The results are given in Table VI. It will be seen that after solution of 30,000 million cocci per c.cm. there had been a fourfold increase in the lytic power of the solution of tears.

The fact that bacteria when dissolved by lysozyme do not neutralise the lytic agent doubtless has a very important bearing on the utility of lysozyme in preventing infections.

When we contrast in our minds the powers of the natural "antiseptics" of the body with the chemical antiseptics we are all probably inclined to believe that the former are weak in comparison. Possibly this is because in the past the testing of chemical antiseptics has for the most part been done under conditions which are very favourable to the antiseptic, while the testing of the bactericidal agents normally present in the body has perforce often to be done under conditions unfavourable to them. In the following experiment the natural antiseptic, lysozyme, is compared with the common chemical antiseptics in use, under conditions not unfavourable to the former.

Small discs are cut out of an agar culture plate with a cork-borer, and in the cavities so produced discs of filter paper soaked in natural or chemical antiseptics are placed. The cavities are then filled in with melted agar and the whole surface is planted thickly with bacteria. The natural antiseptics chosen are tears and nasal mucus, both of which are rich in lysozyme, and the microbe chosen is *M. lysodeikticus* which, while it presents about the usual resistance to the chemical antiseptics, is specially susceptible to lysozyme action. There is no growth of the coccus near the embedded tears and nasal mucus, while there is a thick sheet of growth over all the chemical antiseptics—namely, iodine, 1 in 100; carbolic acid, 1 in 20; mercuric chloride, 1 in 1000; flavine, 1 in 1000; brilliant green, 1 in 500; gentian violet, 1 in 100; and mercurochrome, 1 in 100. Such an experiment shows that, given favourable conditions, the natural antiseptics have a far greater antibacterial effect than the commonly used chemical antiseptics in the strengths in which they are employed.

Relation of Lysozyme to Natural Immunity.

It seems hardly likely that the human body should have been endowed with such a powerful antibacterial power unless it were of use. The wide distribution of lysozyme in the cells of the tissues and organs rather suggests that this antibacterial agency is one of the primal protections of the cell against bacterial invasion, while its great concentration in certain tissues and secretions indicates that its elaboration or secretion has become especially enhanced in certain regions which are particularly exposed to infection or which are lacking in other means of protection. The eye, the nose, and the lower respiratory tract are constantly exposed to those organisms commonly met with in the air, and it is towards these organisms that the lysozyme of tears, nasal mucus, and sputum are most powerful. There could be no chance of a microbe such as *M. lysodeikticus* invading the body, as it would be killed and dissolved by the secretions long before it could proliferate and set up an infection.

The use for an efficient bactericidal agency in cartilage is clear, as this tissue is practically without blood-supply, so that if microbes did gain access the bactericidal powers of the blood, which might prove effective in other tissues, would here be without avail. The use of lysozyme in egg-white in enormous concentration is equally clear in that, apart from the mechanical protection of the shell, which is by no means perfect, there is nothing to protect the egg from bacterial invasion.

The very interesting observation was made that human tears had some bactericidal and bacteriolytic power on *Bacillus abortus* and *B. pseudotuberculosis rodentium*, while they apparently had none on *Micrococcus melitensis* and *B. pestis*. It is well known that *B. abortus* is culturally and serologically identical with *M. melitensis*, and the same applies to *B. pseudotuberculosis rodentium* and *B. pestis*. Therefore the two organisms which are not pathogenic for man are destroyed by human secretions, while the two identical organisms which are pathogenic for man are insensitive to these secretions. It may be that th difference in the pathogenicity of these organisn lies in their different susceptibilities to huma lysozyme.

If the organism survives the lysozyme and grow out in its presence, its progeny acquire a resistanc to the lysozyme of all the tissues and secretion including the leucocytes. This acquired resistanc might easily be enhanced until a microbe of pract cally no virulence which has been growing sapr phytically might ultimately become capable infecting the body.

It has not been found possible to increase th lysozyme content of the secretions or of the bloo serum by the administration of vaccines. This is i marked contrast to the well-known bacteriolyt power of the blood serum to organisms like th typhoid bacillus, and it rather suggests that lysozym is related to natural immunity and not to an immunity that may be acquired.

Findlay has shown that in animals fed on a di deficient in vitamin A the onset of keratomalac was coincident with a fall in the lysozyme conte of the tears, and that the onset of keratomalac could be prevented by the instillation of huma tears into the animals' eyes, whereas the instillatio of normal salt solution had no such protective actio Ridley has found that patients with keratitis an conjunctivitis have a reduced lysozyme content i the tears, and that this reduction is sufficient to perm of the growth of organisms like staphylococci, whic are inhibited by tears containing their full complemer of lysozyme.

The view has been very generally held that th function of tears, saliva, sputum, &c., in relation t infections was to rid the body of the microbes b mechanically washing them away. Metchnikoff, his treatise on "Immunity and Infectious Disease expresses himself very clearly and precisely on th point.

"Nature to protect the skin and mucous membran does not use antiseptics. The fluids which bathe t surface of the mouth and other mucous membranes a not bactericidal or very imperfectly so. Nature remov from the mucous membranes and the skin quantities microbes, eliminating them by epithelial desquamati and expelling them with the secretions and liquid excretio Nature has chosen this mechanical procedure just as t surgeons who replace the antisepsis of the mouth, t intestine, and other organs by lavage with physiologic saline."

Such a view must be profoundly modified, and th direct bactericidal action of the tissues and secretio must be considered an important factor in natur immunity.

THE BIRMINGHAM HOSPITALS.—It is expected th the first year's working of the Birmingham Hospital Saturd Fund, in its capacity as the Industrial Section of the H pitals' Contributory Scheme, will be the raising of ov £140,000—more than double the amount raised in 192 This fund is said to be the largest organisation of the ki in the world. A cot given by workpeople employed at t Austin Motor Works has recently been dedicated in t Children's Hospital, Birmingham. The Austin Workpeopl Hospital and Benevolent Fund has during the last 12 ye contributed £57,000 to the hospital and other charita institutions of the city. Dr. F. W. Ellis, the chief medi officer of the Birmingham Board of Guardians, dealing w the work in the year ending on March 31st last of t Dudley-road and Selly Oak Hospitals, reports that the ci "is at last beginning to get within viewing distance obtaining a sufficient number of hospital beds." More th 21,000 patients were treated, there were nearly 1000 ope tions for appendicitis, and over 1000 cases of pneumon The average weekly cost per head was a few pence over

UTE MENINGO-ENCEPHALOMYELITIS OF CHILDHOOD.

REPORT OF SIX CASES.

By W. RUSSELL BRAIN, D.M. Oxf., M.R.C.P. Lond.,

ISTANT PHYSICIAN TO THE LONDON HOSPITAL AND TO THE HOSPITAL FOR EPILEPSY AND PARALYSIS, MAIDA VALE ;

AND

DONALD HUNTER, M.D., M.R.C.P. Lond.,

ASSISTANT PHYSICIAN TO THE LONDON HOSPITAL.

With a Pathological Report on One Case by

Hubert M. Turnbull, D.M. Oxf.,

ECTOR OF THE BERNHARD BARON INSTITUTE OF PATHOLOGY, HE LONDON HOSPITAL ; PROFESSOR OF MORBID ANATOMY IN THE UNIVERSITY OF LONDON.

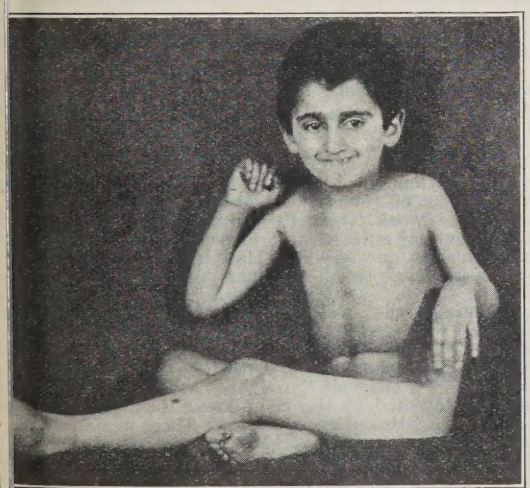
[N June, 1928, we reported in a letter to THE NCET [8] "six cases of acute meningo-encephalo-relitis which differed clinically in many respects m acute epidemic encephalitis lethargica and owed a marked clinical similarity to post-vaccinal cephalitis, though none had recently been vac-ated." This paper contains a full clinical account these cases, together with Prof. Turnbull's report the pathological findings in the fatal case, to which erence has already been made at the Cardiff meeting the British Medical Association.[26]

Report of Cases.

ASE 1.—A. B., male, aged 8 years, Hebrew, who lived at talfields, was admitted to the London Hospital on ril 16th, 1928. On the morning of the day of admission said that he felt "miserable" and complained of a loss eeling in the right hand. In the evening he went to bed usual, but about 8 P.M. he vomited, and was found semi-scious and unable to move his right arm, and was then ught to hospital. The previous history was unimportant ; had been vaccinated in infancy.

ondition on Admission.—On admission the patient was onscious and saliva ran from his lips. His temperature 99·4° F., his pulse 90, and his respiratory rate 32. The

FIG. 1.



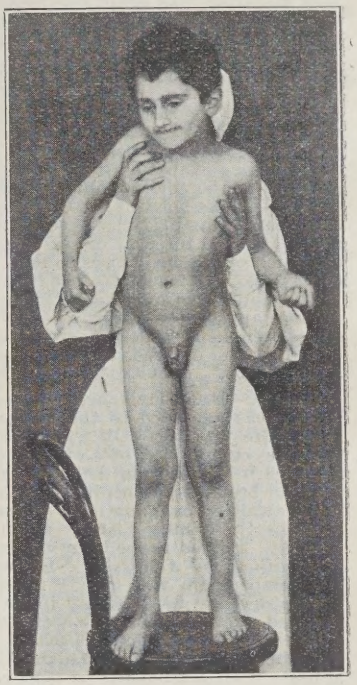
Patient No. 1 during the sixth week of his illness.

fli were normal, the pupils equal, and reacted to light ; te was moderate horizontal conjugate ocular deviation to he left, with a flaccid right hemiplegia. The tendon re xes were brisker on the left side than on the right. The a ominal reflexes were not elicited. The right plantar re x was extensor and the left flexor. There was slight ri dity of the posterior cervical muscles, and Kernig's sign w present. The cerebro-spinal fluid was clear and no c gulum formed. There was one small lymphocyte per c. m., protein 0·073 per cent., sugar 0·077 per cent., chlorides 0·73 per cent. Wassermann reaction negative. The fauces were normal, the cardiovascular system, the lungs, and the abdominal viscera appeared normal. The urine was normal. Blood examination showed a slight leucocytosis, there being 11,480 white cells, with a normal differential leucocyte count.

Progress of Case.—The patient became afebrile on the fifth day of the illness. Consciousness was not fully regained until the seventh day, and complete motor aphasia and apraxia were then found to be present. There was marked trismus, which persisted for a fortnight and rendered feeding difficult. Saliva ran from between the clenched teeth. There was marked weakness of all four limbs, the left being weaker than the right. Some cervical rigidity remained for a fortnight.

Figs. 1 and 2 illustrate the condition of the patient in the sixth week of the illness when he still had complete motor aphasia and double spastic hemiparesis. During the latter part of June speech began to return very gradually, and the patient, who previously throughout the illness had had incontinence of urine and fæces, began to regain sphincter control. Power improved in the limbs. Improvement, once begun, was rapid and by the end of August recovery was almost complete. Speech and intelligence were then normal, and so, too, was voluntary power except for very slight weakness of the lower limbs. There was slight precipitancy of micturition, otherwise there were no residua. (Ref. No. 30597/1928.)

FIG. 2.



Patient No. 1 during the sixth week of his illness.

CASE 2.—C. D., male, aged 9, who lived in Bethnal Green, was admitted to the London Hospital on May 2nd, 1928. On the previous day he went to a cinema and on returning home complained of slight bachache. At 9 P.M. he said he felt "hot and cold," and was put to bed. He vomited once during the night and twice on the next day. During the night movements of the patient's arms were observed which were described by the mother as "jumps, just as if he was going to have a fit." The next day he was very drowsy and the mother stated that she "could not get him to take notice." Previous history : He had measles when 3, scarlet fever when 5, and had never been vaccinated.

Condition on Admission.—On the evening of May 2nd his temperature was 105° F., pulse 140, and respiratory rate 38. He was extremely drowsy. He could be roused to answer questions which were shouted at him, but often fell asleep in the middle of a statement. He was delirious when roused. There was no aphasia. He tended to lie on the left side in an attitude of general flexion. On two occasions he exhibited a spasm of the upper limbs in which the arms were abducted at the shoulders, the elbows and fingers remaining flexed. The eyes were closed and photophobia was extreme, which rendered examination of the fundi impossible at this stage. The pupils were equal and reacted briskly to light ; there was a convergent squint (congenital). Ocular movements could not be tested. Facial movements were rather poor on both sides. The tongue was protruded in the middle line. There was moderate cervical rigidity. The limb musculature was generally hypotonic ; voluntary power was good as far as could be tested. The tendon reflexes in the upper limbs were very sluggish. The knee-jerks were just present and equal, the right ankle-jerk was just present, the left was not obtained. The abdominal reflexes were present in the upper segments only, and brisker on the right side than on the left. The plantar reflexes were flexor. Pin-prick was everywhere appreciated. Kernig's sign was positive. There was no incontinence. No abnormality was found in the fauces,

heart, lungs, or abdomen. The urine contained a trace of albumin. Blood examination was normal.

Lumbar puncture was performed. The cerebro-spinal fluid was clear and colourless and contained one mononuclear cell per c.mm. The protein was 0·047 per cent., the glucose 0·077 per cent., and the chlorides 0·715 per cent.

Progress of Case.—On the following day, May 3rd, he was less drowsy, but still delirious; photophobia was present, but less marked; cervical rigidity was less marked; the condition was otherwise unchanged. The temperature was 104° F. in the morning, falling to 102° F. at night. On May 4th there was again less drowsiness, less photophobia, and less cervical rigidity. Delirium had ceased. The temperature, however, rose to 105° F. at night. After this date improvement was rapid. The temperature after reaching 105° F. on the evening of May 5th fell rapidly and reached 98° F. on the morning of May 7th, and did not again rise above normal. The disappearance of the signs and symptoms of meningeal irritation left the child much exhausted, but convalescence was fairly rapid. The fundi could not be examined in the early stages of the illness on account of the photophobia. Later some swelling of the optic discs was noted. Mr. C. B. Goulden was good enough to examine this patient for us both in the early stages and again after an interval of six months. He considered the condition of the optic discs to be a "pseudo-papillitis" and to have no relationship to the illness.

The child was discharged from hospital on June 20th, having apparently made a complete recovery. He has since been kept under observation as an out-patient, and examination of the nervous system now reveals no abnormality. (Ref. No. 30695/1928.)

CASE 3.—E. F., male, aged 10 years, who lived at Bethnal Green, was admitted to the London Hospital on May 1st, 1928. He was perfectly well until the day of admission, when he complained of a slight headache in the morning. At 11 A.M. he became delirious and unsteady in walking, He was brought to hospital in the afternoon and vomited while awaiting examination. There was nothing of importance in the family history or in the patient's previous history. He had never been vaccinated.

Condition on Admission.—He was pale and looked ill. His temperature was 97·5° F., his pulse-rate 98, and his respiratory rate 24. He lay in an attitude of flexion and resented examination. He was delirious and appeared to think he was being kept at school, and addressed everyone who approached him as "Madam." He had marked nominal aphasia with a tendency to perseveration, and was totally unable to name common objects. He was also apraxic—e.g., retracting the lips when asked to protrude the tongue. There was no cervical rigidity. The fundi were normal; the pupils were equal and reacted well to light and accommodation. The ocular movements were full and there was no squint, ptosis, or nystagmus. There was slight weakness of the lower facial movements on the right side; movements of the soft palate and tongue were normal. No weakness or ataxia of the limbs could be detected; muscle tone appeared to be normal. Pin-prick was everywhere appreciated. The tendon and abdominal reflexes were present and equal. The right plantar reflex was doubtfully extensor, the left flexor. The fauces, cardiovascular system, lungs, and abdomen were normal. The urine was normal. Lumbar puncture was performed within one hour of admission. The cerebro-spinal fluid was clear and colourless. There were no cells. The protein was 0·038 per cent.; the sugar, 0·069 per cent., and the chlorides, 0·73 per cent. The Wassermann reaction was normal. A blood examination showed no abnormality.

Progress of Case.—The effect of lumbar puncture was remarkable. He became much quieter and sank into a quiet sleep. Four hours later he was no longer disorientated and recognised that he was in hospital. On the following day, May 2nd, delirium and dysphasia had completely disappeared. He had no recollection of the episodes of the previous night, did not remember coming to hospital, and did not recognise the doctors who had attended him. The right facial weakness was gone and both plantar reflexes were flexor, but there was now moderate weakness of the left lower facial muscles, which persisted for three days. His temperature on the second day of the illness was 99° F., but after this he was apyrexial. A week after the onset he was apparently completely well and has remained so since. (Ref. No. 30686/1928.)

CASE 4.—G. H., female, aged 8, who lived at Bow, was admitted to the London Hospital under the care of Dr. Cecil Wall on May 5th, 1928. Her illness began three days previously, when she complained of headache, vomited several times, and became lethargic, taking no notice when addressed. There was nothing of importance in the previous or the family history.

Condition on Admission.—The child appeared to be very ill, with a temperature of 105·4° F., a pulse-rate of 160, and respiratory rate of 50. The skin was hot and dry, the tongue furred, and the lips covered with sordes. T patient was very drowsy, but could be roused to answ questions intelligently. There was no dysphasia. T fundi were normal, the pupils were widely dilated a reacted very sluggishly to light and on accommodatio The ocular movements were full. Movements of the fac soft palate, and tongue appeared normal. There was appreciable loss of power in the limbs, which were hypoton The abdominal reflexes were present and equal. The tend reflexes were not obtained; there were bilateral extens plantar responses. Pin-prick was everywhere appreciat There was moderate cervical rigidity and Kernig's si was present. The tonsils were enlarged. The cardi vascular system, the lungs, and the abdomen were norm The urine contained a trace of albumin. Lumbar punctu was performed on the day following admission. The cerebr spinal fluid contained four mononuclear cells per c.mm. T protein content was 0·015 per cent.; the chlorides we 0·73 per cent. The Wassermann reaction was negative.

Progress of Case.—In the first three days after admissi the patient continued to be alternately drowsy and restl and complained of pain in the head and back. T temperature fell by lysis to normal on the fifth day aft admission. An eruption of herpes febrilis appeared on t lips on the second day. Cervical rigidity persisted three days. On the fifth day the patient was much bett and was no longer drowsy. The pupillary reactions we still very sluggish, but the plantar reflexes were flex Recovery was rapid and complete. When re-examined Dec. 16th, 1928, the child was said to be in normal heal and attending school. Examination failed to reveal a abnormality in the nervous system or elsewhere. (R No. 40722/1928.)

CASE 5.—I. J., female, aged 18, who lived at Shepher Bush, was admitted to the Hospital for Epilepsy a Paralysis, Maida Vale, on June 4th, 1928. On May 28 she swam in some open-air baths in the morning. In t evening she felt sick, giddy, and faint. Frontal headac and vomiting developed. On the following day the headac was more severe and she saw Dr. J. M. Fonseca, who h kindly furnished us with information as to her conditi at that time. She was found to have pharyngitis, and h temperature was 103° F. That evening she was deliric and complained of abdominal pain. On the following d she was less feverish and no longer delirious, but there w still pain in the abdomen, and, in addition, in the ba On the fourth day of the illness the temperature was norn and she was free from headache. On the fifth day s attempted to get up, but found the legs were very wea She could only walk with great difficulty and "shuffl along." She had an abnormal feeling in the abdomen, " if she had no stomach." There was no impairment sphincter control. She had been vaccinated in infancy a had scarlet fever and measles as a child. Previous to t illness her general health had been excellent. There w nothing of importance in the family history.

Condition on Admission.—On examination on the sever day of the illness she was a well-nourished girl—brig intelligent, and in no way lethargic. She was apyrexi The fundi were normal, and the only abnormality in t cranial nerves was that the pupils, which were moderat dilated, reacted briskly to light, but failed to react accommodation. The upper limbs were normal. There w no weakness of the abdominal musculature. Both lov limbs were weak, the left slightly more than the rig The abdominal reflexes were present on the right side, almost absent on the left. The tendon-jerks in the lov limbs were exaggerated, the right knee-jerk brisker than the left, the left ankle-jerk brisker than the right. T right plantar reflex was flexor, the left a doubtful extens Sensation: There was hypalgesia to pin-prick on the ri side of the trunk from the level of the third rib to groin and below both knees, but prick was better appreciat on the left leg than on the right. A hot test-tube felt l hot when applied to the right lower limb below the k than when applied above the knee. There was no cutane anæsthesia, no loss of postural sensibility, nor of appreciat of vibration. The fauces were somewhat inflamed, cardiovascular system, the lungs, and the abdominal visc appeared normal. The urine was normal. Lumbar punct was performed on the seventh day of the illness, the day admission to hospital. The cerebro-spinal fluid was cl and colourless. The total protein was 0·030 per cen Nonne-Apelt negative. One cell per c.mm. Lange norm Wassermann reaction negative. The blood Wasserma reaction was negative.

Progress of Case.—Improvement was rapid. Three we after the onset of the illness all sensory loss, and concurren the abnormal sensations referred to the abdomen, l disappeared. There was considerable increase in volunt power in the lower limbs. There was still, however, v little reaction of the pupils to accommodation, though light reflex was brisk. The patient was discharged fr

spital a month after admission and has since been kept der observation as an out-patient.

When last seen, Dec. 3rd, 1928, she had no symptoms, d returned to work, and was able to stand all day without igue. The reaction of the pupils to accommodation was ll somewhat sluggish, the abdominal reflexes were minished on the left side as compared with the right, and ere was slight weakness of the left lower limb. The knee- d ankle-jerks were brisker on the left than on the right le and the left plantar reflex was less briskly flexor than e right. There was no sensory loss.

CASE 6.—K. L., male, aged 3, who lived at Woodford, sex, was admitted to the London Hospital under the care Dr. Cecil Wall on May 5th, 1928. Dr. D. W. Tacey, der whose care he was prior to his admission, has kindly t us the following information as to his previous condition. . Tacey first saw the patient on May 3rd, when the relatives ted that the child had been restless for two days and ghts, had vomited occasionally, and had lost its appetite. e child looked listless and "seedy," but not very ill. e temperature was normal, the respiration rapid, but not oured. Physical examination revealed nothing abnormal cept some faucial congestion and a furred tongue. On e following day, May 4th, the child seemed brighter. The nperature was normal, but the respiration was still rapid. May 5th he was much worse, having passed a restless ght, screaming suddenly and vomiting. When examined Dr. Tacey he was very lethargic and difficult to rouse, ng curled up in a flexed attitude. He screamed if touched on the right side, but did not mind being touched on the t side. There was no head retraction, but Kernig's sign s present. Tache cérébrale was elicited on the chest and domen. Respiration was very rapid and laboured. The ild was then admitted to the London Hospital. Previous story: Vaccinated in infancy.

Condition on Admission.—On admission he was semi- nscious and resented interference. The temperature was 1° F., the pulse 128, and the respiratory rate 46. He lay his side with the head somewhat retracted and the limbs xed. There was slight rigidity of the posterior cervical uscles and Kernig's sign was present. The fundi were rmal, the pupils moderately dilated and equal, and reacted light. There was no squint. No gross weakness of the abs could be detected. The knee-jerks were present and ual and the plantar reflexes indefinite. The heart, lungs, d abdomen were normal. The cerebro-spinal fluid was ear and no coagulum formed. It contained seven cells per mm., type monocytes. The protein was 0·030 per cent., d the Wassermann reaction was negative.

Progress of Case.—The child became increasingly comatose d died on the day following admission.

The following is Prof. H. M. Turnbull's report on the result the post-mortem examination. (Ref. No. 30720/1928.)

REPORT ON POST-MORTEM FINDINGS IN CASE 6, BY PROF. H. M. TURNBULL.

Summary (P.M. 205, 1928).—Toxæmia. Ring emorrhages in congested and œdematous brain. ipoid nephrosis of kidneys. Extreme fatty, partly poid, degeneration of liver. Parenchymatous generation of myocardium. Central necroses in alpighian bodies of spleen. Congestion of posterior rts of lungs. Slight mucous catarrh of stomach. jection of Peyer's patches. Group of caseous tuber- ulous mesenteric glands (largest 1·3 × 0·8 × 0·7 cm.) lower and middle tiers of mesentery and in ileo-colic gle. No atheroma. Straight line, less than half a illimetre deep, of provisional calcification in ribs and mur. Red marrow throughout femur. Slightly asted, well-developed boy with sunken eyes.

Weights: Body, 11·3 kg. (length 0·915 metre); rain, 1162·3 g.; liver, 375·8 g.; heart, 56·7 g.; dneys, 85·0 g.; spleen, 14·2 g.; thymus, 10·2 g.; yroid, 1·9 g.; pancreas, 16·1 g.; suprarenal bodies, 5 g.; pituitary body, 0·2 g.; bodies of testicles, 4 g.

Macroscopic Examination.

The brain was bulky and showed a pressure cone cm. long. The leptomeninges were injected. On ction the cortex was a deep purple, whilst blood elled from the vessels in the medulla. The kidneys ere enlarged and swollen. The capsule was thin and sily removed from a smooth, pale, yellowish outer rface. The cortex bulged above the medulla, and owed somewhat opaque yellow vertical streaks in e intermediate zone. The liver showed the general nlargement, the rounding of borders and the swelling of the cut surface characteristic of parenchymatous degeneration.

Microscopic Examination.

Portions of the liver, kidney, and spleen were fixed in 4 per cent. saline formaldehyde and embedded in paraffin. Other portions of the liver and kidney after similar fixation were cut upon the freezing microtome; some sections were stained by Herxheimer's method and others were mounted unstained in glycerine jelly for examination with the polariscope. The brain and cord were first fixed in 4 per cent. saline formaldehyde. Numerous pieces were then taken from the frontal, parietal, and occipital lobes, the Sylvian fissures, the centra semiovalia, and the cerebellum; numerous complete segments were taken from the basal ganglia, the anterior and posterior part of the midbrain, the pons, medulla oblongata, and all divisions of the spinal cord. One series was cut upon the freezing microtome, and sections were stained by Herxheimer's method. Another series was embedded in paraffin, and sections were stained with toluidin-blue according to Lenhossek's method, Mallory's phosphotungstic hæmatoxylin after treatment with Zenker's fluid, Ehrlich's hæmatoxylin and eosin, Weigert's iron hæmatoxylin, and van Gieson's stain, Weigert's fuchselin and neutral red, and muci-carmine and hæmatoxylin. Other two series were placed in Müller's fluid and were stained respectively by the Busch-Marchi method after embedding in celloidin, and by the Weigert-Pal method after embedding in paraffin.

Kidney.—The kidney is congested. Most of the cells lining the first convoluted tubules, including the straight portions, are loaded with fatty granules and crystals, which after melting give doubly refractive liquid crystals under the polariscope; the remaining cells show severe albuminous degeneration. In many cells there is karyolysis or complete loss of nuclei. The lumina of the first convoluted tubules contain albuminous granules, a very few desquamated epithelial cells, and a few fatty spheres; there are also one or two red corpuscles in a few lumina, possibly carried there by the knife. A few minute granules of fatty substance are present in some of the cells lining the ascending limbs of the loops of Henle. Hyaline droplet degeneration is not present. There are no casts in the ascending limbs of Henle, nor in the collecting and discharging tubules. In the glomeruli the capsule of Bowman sometimes contains albuminous granules, which appear to be due, at any rate in part, to necrosis following swelling and desquamation of cells of the epithelial lining. Occasionally a glomerular lobe devoid of epithelium is united by albuminous granules to a portion of the parietal wall of the capsule devoid also of epithelium, indicating the commencement of glomerular adhesion. Glomerular necrosis, proliferative glomerulitis, and proliferative capsulitis are absent. There is no inflammatory infiltration of tubules or interstitial tissue.

Liver.—The cells throughout the lobules are loaded with fatty substance. In the outer third to one-half of the lobules the cells are converted by large globules into signet rings; in the inner part of the lobules the cells contain granules as well as large globules of fat. The Kupffer cells also contain fat. After melting the fat a considerable number of doubly refractile liquid crystals are formed. In the hepatic cells in the centres of the lobules the nuclei are frequently very small, pale, and of irregular shape; in some cells the nucleus is absent.

Spleen.—The centres of the Malpighian bodies are occupied by large, swollen, polygonal reticulum cells; in some Malpighian bodies a few of these are necrosed. The reticular strands of the pulp contain few free cells; eosinophil leucocytes are scattered throughout, and there are a very few large basophil monocytes undergoing karyokinesis. The venous capillaries show some desquamation of endothelium, and contain more lymphocytes than granular cells; neutrophil leucocytes are present in considerable number in a few areas only, and there are a few myelocytes. The intima of some of the arterioles shows hyaline degeneration.

Central Nervous System.—Œdema of the central nervous system is shown by wide perivascular spaces of His, by wide perineuronal spaces, and by a reticular rarefaction of the tissues round many vessels. The

meninges are conspicuously engorged and there is great *engorgement* of the substance of the brain and brain-stem, and less engorgement of the spinal cord. The red corpuscles within the central nervous system have with few exceptions been laked. *Hæmorrhages* into the perivascular space of His, less commonly into the adventitial space, are present in small number in the white matter of the cerebrum, the cerebellum, and the pons. Ring hæmorrhages are frequent in all parts of the centra semiovalia and the white matter of the cerebellum; in these sites they are usually of small size. In the internal capsules, particularly the left, they are more numerous and larger; in the anterior commissure they are very numerous and of great size.

In the centre of the *ring hæmorrhages* is a capillary or small vein. The lumen contains closely packed red corpuscles and, occasionally, a considerable number of neutrophil leucocytes. Hyaline thrombi, which are usually present within ring hæmorrhages, appear to be absent from this case; no fibrin was demonstrated by the Weigert-Gram method. Round the vessel is a zone containing conspicuous spherical, pyriform, and, less commonly, cylindrical bodies. The larger bodies measure as much as nine micra in diameter. In hæmatoxylin and van Gieson preparations these bodies are hyaline. In Mallory's phospho-tungstic hæmatoxylin they frequently show numerous small blue dots, of one to one and a half micra in diameter, closely packed in a pinkish-yellow matrix; this appearance thus suggests a spore-bearing body. Comparison of the appearances in all stains shows that these bodies are focal swellings of axis-cylinders surrounded by a thin ballooned medullary sheath. In this central zone there are usually several neutrophil leucocytes, large mononuclear leucocytes, and glial cells which have a sharply defined body and, usually, a large, pale nucleus. Outside this zone of swollen axis-cylinders is a zone in which the tissues are separated by laked red corpuscles. In this zone glial cells and nuclei are relatively scanty; one or two neutrophil leucocytes are sometimes present. No fibrin is demonstrated by the Weigert-Gram method within the ring hæmorrhages, and no fat by either Herxheimer's or Marchi's methods.

In the sections stained by Lenhossek's method the *bodies of the neurons* and their neurochromatin show in general remarkably little alteration, considering that the material was not fixed until some 32 hours after death. In certain nuclei, however, there are obvious degenerative changes. In the dorsal vago-accessory nucleus there is perinuclear tigrolysis, several nuclei are eccentric, and a few cells have lost their nucleoli. In the dorso-lateral part of the oculo-motor nucleus, particularly at the level of the posterior corpora quadrigemina, the tigrolysis is greater, and eccentricity of nuclei and loss of nucleoli are frequent. Similar changes are seen in the large cells of the putamen and globus pallidus. On the left side the degeneration is very severe in the external division of the globus pallidus, some cells having lost their nuclei; it is less severe in the mesial division and still less in the putamen. On the right side the degeneration is not so great, and a similar difference between the degrees of affection of the three nuclei is doubtful.

In sections stained by the methods of Herxheimer and Marchi fine droplets of fat are demonstrated within a few endothelial cells lining vessels. *Fat-granule cells* are numerous. They are of swollen fusiform or more often rounded shape, and are filled with coarse granules of fatty substance. They clothe the outer surface of capillaries and venules, and lie clearly within the adventitial sheath of larger vessels. A very few lie in the pia within cerebral sulci. They are present in small number round a few vessels within the cerebral cortex, being most numerous in the deeper layers. In the cerebral white matter they are numerous and conspicuous round many of the vessels in the centre of the convolutions and become less numerous deeper within the centra semiovalia. They are present throughout the basal ganglia, but are sparse except in the vessels between the two division of the globus pallidus, vessels in the internal capsule and putamen, and in the optic thalamus near the internal capsule. They are also present throughout the midbrain, but are numerous only in the adventitia of many large vessels in the crusta, large vessels beneath the lateral fillet, and smaller vessels in the grey matter round the iter. In the pons they are conspicuous round vessels close to the ventricular surface, in the nucleus funiculus teres and in the ventro-lateral angle of the fourth ventricle. In the cerebellum they surround a few vessels immediately beneath the cortex and several vessels deep within the white matter. In the medulla oblongata they are very scanty and in the spinal cord are found in very small number in the white matter of the cervical segments alone. They are also present round a few vessels in the optic tracts.

Free Fat.—In Herxheimer, Sudan, and Marchi preparations numerous extra-cellular fatty globules are seen in the external segment of the globus pallidus on both sides, being more abundant in the dorsal two-thirds of the nucleus; similar, but much less numerous, droplets lie in the mesial segment of the globus pallidus. The droplets measure up to 15 micra in diameter, and are almost always in close relation to white fibres. A few small groups of similar droplets lie in the optic tracts. Fine droplets of fat are demonstrated in small number by the Marchi method alone in the internal capsules, the white matter of the midbrain, particularly the lateral fillets, and in the posterior spinal roots; and in still smaller number in the white matter of the pons, medulla, and spinal cord, and in the anterior spinal roots and the roots of the fourth and fifth cranial nerves. No demyelination is recognisable in the Weigert-Pal preparations. There is no mucous degeneration. Apart from the fat-granule cells there is no infiltration of the adventitia of vessels or of the meninges.

Interpretation of Microscopic Findings.

Fat-granule cells occur normally during the development of the medullary sheaths (Flechsig, 1876; Storch, 1900). Observation was, therefore, kept in the post-mortem room for another child of three years to serve as a control. A girl who had died from acute rheumatic endocarditis and acute and chronic pericarditis (P.M. 373, 1928) was obtained. In Herxheimer preparations of the cerebrum and basal ganglia perivascular fat-granule cells were found in very similar number and distribution. It is impossible, therefore, to accept the fat-granule cells in the case under discussion as evidence of a pathological condition or, at any rate, of a specific pathological condition.

In the examination of the central nervous system of a rabbit which died three days after intracerebral inoculation with vaccinal lymph by Prof. J. McIntosh I had found no evidence of demyelination in Weigert-Pal and Marchi preparations except in the mesial divisions of the ventro-lateral limbs of the lenticular nuclei. Here numerous fat droplets were demonstrated by the Marchi method. Infiltration of the adventitial sheaths of perforating vessels with lymphocytes and large mononuclear leucocytes extended from the cerebrum to the sacral cord. The finding in this rabbit and the young child of free fat confined to the lenticular nucleus suggested that destruction of myelin might occur in the lenticular nucleus in any acute infection, at any rate in young children. The brain of the child of three years who died in an attack of acute rheumatic fever was employed to test this possibility. Numerous large droplets of fat were again demonstrated by Herxheimer's method in the external division of the globus pallidus, and a few in the mesial division. The control material examined is much too scanty for any general conclusion; it is possible that free fat is normally present in the globus pallidus of 3 year old children, but material to test this was not available. The control is sufficient, however, to make it impossible to accept the degeneration seen in the globus pallidus as evidence of a specific pathological change

n the present case. The distribution of intra- and xtra-cellular fat, as demonstrated by Herxheimer's nethod, is the same in both the children aged 3 years.

The specific changes in the central nervous system re thus reduced to œdema, congestion, degeneration f certain groups of ganglion cells, and ring hæmorhages. The ring hæmorrhages, when compared with hose associated with fat embolism, broncho-neumonia, cerebral hæmorrhage, and eclamptic æmorrhage in specimens which have been reserved n our cabinets, differ in the apparent absence of hrombi in the central vessels and in the much greater welling of the axis-cylinders. The swelling of the axis-ylinders approaches to that which was found in an xample of Salvarsan Kopf-Tod. Here, in association vith ring or other hæmorrhages, often independently f hæmorrhage, there are throughout the central ervous system numerous focal areas of astonishingly reat swelling of axis-cylinders and ballooning of their nedullary sheaths; hyaline thrombi are usually resent. The ring hæmorrhages in the present case an be attributed to some toxæmia. A toxæmia vould also explain the degeneration of the bodies of neurons in the sites specified.

It remains to discuss the relation of the changes in he central nervous system to those in the liver and idneys. The size and distribution of the globules of at and lipoid in the liver resemble those of fatty nfiltration rather than of fatty degeneration, as they re usually distinguished. But in young children the lassical morphological characteristics of fatty infil-ration may be found under circumstances which learly show that the metabolism of fat in the liver as been interfered with, so that the accumulation is n expression of degeneration in the sense of a isturbance of function; thus there is frequently reat fatty infiltration of the liver in infants who have een greatly wasted by chronic gastro-enteritis. Further, in the present case there is definite evidence f degeneration of cells in the centres of the lobules. The liver is evidently the site of a parenchymatous legeneration very similar to that in the kidney. In the kidney there is a lipoid and albuminous degenera-ion which is not accompanied by any exudative or nfiltrative inflammatory reaction. The condition is a pure parenchymatous degeneration; that is, a nephrosis in the strict sense of the term as defined by its inventor, Friedrich Müller (1905). Now hæmor-rhages in the brain undoubtedly occur in cases of nephritis with uræmia. In the present case, however, there can be no question of uræmia. Dr. Dorothy Russell, in an investigation of nephritis shortly to be published, has found that evidence of nitrogen retention was obtained by the appropriate tests in the wards in no case in which the kidney showed a similar lipoid nephrosis; further, no evidence of nitrogen retention was found in kidneys in which either a slight cellular infiltration of tubules and interstitial tissue or an interstitial granulation tissue was added to the changes already described. In all examples of such lipoid nephrosis and the corresponding form of nephritis, a form of nephritis which is characterised chiefly by the absence of proliferative glomerular changes, the condition found clinically was one of hydropigenous nephritis alone. In the present example there was not even œdema. There appears, therefore, to be no justification for considering the changes in the brain and liver in this case to be secondary to the changes in the kidney. It is much more likely that the changes in all three organs were caused by a single agent. The cause of lipoid nephrosis and the corresponding kind of nephritis is obscure. Munk (1916) considered syphilis to be a cause. We have had an example of lipoid nephrosis in a man of 47 who had had a primary sore 16 months before the onset of anasarca; but he had received 15 injections of novarsenobillon, and the degeneration may have been due to this drug. Dr. Russell has found that this class of nephrosis and nephritis does not occur in association with recognisable bacterial infections, but that very similar renal changes are associated with certain endogenous and exogenous toxins; this class of nephritis appears to be caused by toxins other than bacterial. In this connexion it may be mentioned that the histological examination of the spleen in the present case showed no evidence of bacterial infection.

For these reasons the changes in the brain, liver, and kidney have been ascribed in the summary of the necropsy to some unknown toxæmia.

Discussion Resumed by Drs. Brain and Hunter.

Animal Inoculation Experiments.—Dr. S. Phillips Bedson kindly carried out animal inoculations with material obtained from five of our six patients. These experiments and their results are tabulated as follows:—

Case.	Material examined.	Date collection in 1928.	Cultural examination.	Animals inoc.	Mode of inoc.	Result.
1	C.S.F.	25/4	S.	1 rabbit	1·5 c.cm. I.c.	Neg.
				1 monkey†	1·0 c.cm. I.c. and 4·0 c.cm. I.p.	
2	„	2/5	S.	1 rabbit	1·5 c.cm. I.c. and 5·0 c.cm. I.v.	Neg.
				1 monkey†	1·0 c.cm. I.c. and 3·0 c.cm. I.p.	
3	„	1/5	S.	1 rabbit	1·5 c.cm. I.c. and 3·0 c.cm. I.v.	Neg.
4	„	6/5	S.	1 rabbit	1·5 c.cm. I.c.	Neg.
6	Cerv. and dorsal cord.	7/5*	S.		10% emulsion of cord in M/50 phosp. pH, 7·6 :—	
				2 rabbits	1·5 c.cm. I.c.	
				1 rabbit	Inoc. cutaneously, I.d. and corneally.	
				1 monkey‡	1·5 c.cm. I.c. and 5·0 I.p.	Neg.

Cerv. = cervical. S. = Sterile. I.c. = intracerebrally. I.p. = intraperitoneally. I.v. = Intravenously. I.d. = Intradermally.
* Stored in 50 per cent. glycerol in ice-chest until 29/5/28.
† African bonnet. ‡ *M. rhesus.*

Test of Neutralising Power of Convalescent Serum for Herpes Virus.

Case.	Date of bleeding.	—
1	24/5/28	Serum diluted 1 in 5 neutralised 50 M.I.D. herpes virus.
		Serum diluted 1 in 10 did not completely neutralise 50 M.I.D. herpes virus.
2	„	Serum diluted 1 in 1 almost completely neutralised 50 M.I.D. herpes virus.
		Serum diluted 1 in 5 gave no neutralisation.

Results entirely comparable with those obtained with normal lumbar serum.

Summary of Clinical Features.

It will be useful at this point to summarise the clinical features presented by our patients. Six patients came under our observation ranging in age from 3 to 18. All six patients developed their symptoms within a period of six weeks, the first on April 16th, 1928, the next three cases on May 1st, another on May 2nd, and the last on May 28th. Four patients thus manifested their first symptoms during the 48 hours of May 1st and 2nd. Two of these lived at Bethnal Green, one at Bow, and one at Woodford, Essex. The first patient lived at Spitalfields and the sixth at Shepherd's Bush. All thus lived within the London area and all save one in East London. The coincidence of time and, with the exception of the last patient, of place justifies us, we believe, in regarding our six cases as part of a small

epidemic, in which it is likely there were other cases which did not come under our observation.

The onset in every case was acute. Pyrexia was present in every case, and in two patients the temperature reached 105° F. The course of the illness was unlike that of any acute disease of the nervous system with which we are familiar in that, with the exception of the patient that died, all have made a complete or practically complete recovery, and this has occurred in spite of marked variations in the severity and duration of the illness. No. 3 might almost be described as an abortive case since he showed marked improvement a few hours after the onset and was well in four days. No. 2, in whom the symptoms were purely "meningeal" and who showed no signs of involvement of the neuraxis, recovered in a fortnight. No. 4, who showed a predominance of "meningeal" symptoms with the addition of loss of the reflex contraction of the pupils to accommodation and bilateral extensor plantar responses, also recovered in about a fortnight. In No. 5 the predominant symptom was a myelitis with the addition of abolition of the reaction of the pupils to accommodation. This patient recovered from the general symptoms in four days, and the power in the lower limbs had returned almost to normal in a month, but after six months, though subjectively normal, she still showed slight signs of her lesions. No. 1 was the most severely affected of the five surviving patients. In his case "meningeal" signs were insignificant compared with the extensive involvement of the cerebral hemispheres leading to complete aphasia and double hemiplegia. His recovery took several months, but it has been as complete as in the mildest case, and his speech and voluntary power are now normal.

It will be noted that while cervical rigidity and Kernig's sign are almost constant the main variation is in the extent to which involvement of the neuraxis occurs, and this is the main factor in determining the rate of recovery. Two patients showed evidence of extension of the morbid process to an intact area of the nervous system while improvement was occurring in the region first attacked.

Diagnosis from Encephalitis Lethargica.

Our patients differed in many respects from patients suffering from encephalitis lethargica. They presented a number of symptoms very rare in that disease, while several of its more common manifestations were lacking. A fulminating onset, cervical rigidity, Kernig's sign, and trismus are rarely to be found in encephalitis lethargica, and aphasia and hemiplegia are almost equally uncommon. On the other hand, none of our patients showed paresis of individual ocular muscles, and only one-third exhibited pupillary abnormalities. The completeness and in most cases the rapidity of our patients' recovery is unfortunately almost unknown in encephalitis lethargica. Six months is too short an interval to justify stress being laid upon the absence of sequelæ, but we may justifiably emphasise that none of our patients has exhibited that aftermath of invalidism which so frequently follows the acute stage of lethargic encephalitis. Lack of space prevents us from discussing the differential diagnosis from other acute diseases involving the nervous system.

Conditions Presenting Points of Clinical Similarity.

Post-vaccinal Encephalitis.—The clinical resemblance between our group of cases and the numerous reported cases of post-vaccinal encephalitis is striking. Common to both conditions is the rapid onset, with headache, vomiting, drowsiness, and fever, and the frequent occurrence of meningeal symptoms. In either, patients may exhibit convulsions, flaccid paralysis of the limbs, and trismus. Ocular abnormalities are inconstant in both. The variability of the clinical picture—e.g., the occurrence of both encephalitic and myelitic forms—is also characteristic of both, and so too is the tendency to complete recovery of patients who survive.

Trismus is such an unusual symptom of any form of encephalitis that its occurrence in our patient No. 1 appears deserving of emphasis. It has been observed in post-vaccinal encephalitis by Lucksch,[10] Wiersma,[21] and a number of other workers, and is mentioned several times in the clinical accounts of the cases included in the report of the Committee on Vaccination.[20] More than one case of post-vaccinal encephalitis has on account of this symptom been mistakenly diagnosed as tetanus.

Encephalitis Complicating the Specific Fevers.—Many reported cases of encephalitis complicating the specific fevers, especially measles, chicken-pox, and scarlet fever, resemble our patients in their clinical features. These are too numerous to mention individually. We may note in passing that Winnicott and Gibbs [23] quote a fatal case of post-varicellar encephalitis in which meningeal signs and trismus were present, and these authors emphasise the absence of residua in non-fatal cases. Symonds [24] also recently reported a fatal case of encephalitis complicating measles in which trismus was present.

Acute Disseminated Encephalomyelitis.—Under this title a number of conditions characterised by various pathological pictures have been described. Recently Redlich,[19] Pette,[18] Montzka,[14] and Martin [13] have reported cases presenting clinical similarities to our own, and also characterised by their tendency to complete recovery.

Unclassified Forms of Acute Encephalomyelitis in Children.—From time to time observers have reported acute illnesses involving the central nervous system in children and often occurring in small epidemics. These present many points of clinical similarity to our patients, though in several epidemics the mortality has been high. Marsh [12] in 1910 described four cases of "acute non-suppurative encephalitis in children." M. H. Gordon [5] reported 12 cases, all fatal, most of which occurred in the summer of 1913. Anderson,[1] and Brown and Symmers [2] observed between them 16 cases in the United States in the summers of 1923 and 1924. Grinker and Stone[7] have recently described 13 cases of acute toxic encephalitis in childhood complicating local or generalised pyogenic infection.

The Strümpell-Leichtenstern Form of Encephalitis.—The condition to which Strümpell in 1884 and later Leichtenstern first drew attention has since undergone several vicissitudes of interpretation. Strümpell described an acute encephalitis of childhood characterised, in addition to the general symptoms of encephalitis, by convulsions and hemiplegia. This was at first believed to be due to the virus of poliomyelitis, but later came to be regarded as a form of "acute hæmorrhagic encephalitis." Since it appears that the clinical picture of "Strümpell-Leichtenstern encephalitis" may be associated with a number of different pathological states, it is probably best regarded as a clinical syndrome only. Such a syndrome did not occur in our series of cases, though it has been described in such allied conditions as the "acute serous encephalitis" of Brown and Symmers.

The Association of Disturbance of Renal Function with Encephalitis.

Since, in the fatal case in our series, lipoid degeneration of the kidneys was associated with acute degenerative changes in the brain, it is interesting to note that disturbance of renal function has previously been reported in association with acute encephalitis by Ironside and Hinds Howell,[9] M. B. Gordon,[4] and Anderson, and is described by Oppenheim.[16] A similar association of peculiar interest was found by Russell and Oddie [21] in a patient dying of post-vaccinal encephalitis.

Pathological Considerations.

In spite of the clinical similarity of the conditions just described their pathological basis appears at first sight to show considerable diversity. Three groups may in fact be distinguished, though as their distinction is based upon comparatively gross and superficial

aracteristics, it is unlikely that it corresponds to ıy true difference between the pathological processes work. Thus we find:

1. Cases characterised by acute degeneration of the ınglion cells of the brain with hyperæmia and often arked œdema, but without macroscopic hæmor-ıages. This group includes the cases described by ordon, Brown and Symmers, and Grinker and Stone. ussell and Oddie's case of post-vaccinal encephalitis ıould probably also be placed in this group though ıe appearance of the ganglion cells is not mentioned.

2. Cases in which the conspicuous feature is ultiple macroscopic hæmorrhages, so-called "acute æmorrhagic encephalitis." This group includes cases encephalitis following scarlet fever,[23 25] measles,[26 29] fluenza, pyogenic infection,[3 22] and cases occurring ithout any obvious predisposing cause.

3. Cases characterised by perivascular demyelina-on. This histological feature has now been observed a wide range of conditions, including post-vaccinal ncephalitis,[26 27] encephalitis complicating measles,[6 30] ariola,[11] paralysis arising during antirabic treatment,[26] ıd acute disseminated encephalomyelitis.[19]

It is probable that there is no essential pathological ifference between groups 1 and 2, the cerebral ıanifestations in both being the response to a ɔxæmia, which varies in its effect upon nerve-cells ıd blood-vessels, so producing varying degrees of ædema and hæmorrhage. These groups include the ases with renal damage, and our cases would seem to elong to them. Whether any relationship will be stablished between the first two groups and the cases ıowing perivascular demyelination remains to be een, but it is noteworthy that some cases of ence-halitis complicating measles have shown this feature, hile others have been examples of "acute hæmor-ıagic encephalitis."

It may be questioned whether encephalomyelitis is ıe right term to apply to a group of cases in which he cerebral symptoms are the result of a toxæmia ıd which present no histological evidence of inflam-ıatory reaction in the nervous tissues. It seems kely that with further knowledge the existence of ıch states will be recognised by appropriate termino-ɔgy. For the present, however, it seems best in view f their clinical affinities to retain the term encephalo-ıyelitis for these cases.

Conclusions.

Since no satisfactory pathological or bacteriological lassification of certain acute forms of encephalitis is t present available, we feel justified in emphasising linical points of similarity. Our cases appear to show hat a clinical picture similar to that of encephalitis ollowing vaccination, measles, and other specific evers may occur in the absence of any recognisable redisposing cause. A scientific classification of these orms of encephalomyelitis can only be soundly based ıpon much greater knowledge—clinical, pathological, ıd bacteriological—than we yet possess.

We are indebted to Prof. Turnbull for the time and onsideration he has given to the pathological changes n Case 6; to Dr. S. Phillips Bedson for carrying out ınimal inoculation experiments; to Dr. Cecil Wall for llowing us to include Cases Nos. 4 and 6; to Mr. . B. Goulden, for examining patient No. 2; to Drs. E. G. Frewer and L. Hartston, house physicians to the London Hospital; and Dr. C. E. Woodrow, resident nedical officer to the Hospital for Epilepsy and Paralysis, Maida Vale, for their valuable coöperation n the observation of our patients; and to Dr. Tacey ınd Dr. Fonseca for placing at our disposal their notes ɔn their patients.

PEMPHIGUS NEONATORUM.

A SERIES OF FIFTY CASES.

By F. GARLAND COLLINS, M.R.C.S. Eng., D.P.H.,
MEDICAL OFFICER OF HEALTH AND CHIEF SCHOOL MEDICAL OFFICER, COUNTY BOROUGH OF WEST HAM;

AND

HELEN CAMPBELL, M.B. Edin., D.P.H.,
ASSISTANT MEDICAL OFFICER FOR MATERNITY AND CHILD WELFARE, COUNTY BOROUGH OF WEST HAM.

ALTHOUGH this disease was described as long ago as 1773 as a separate infection affecting infants, there does not appear to have been any serious epidemic in this country for a long period. During recent years, however, there has been a very considerable increase in the number of cases arising in many different areas throughout the country. The Central Midwives Board, indeed, thought fit last year to issue to all midwives a special pamphlet,[1] illustrated with a coloured plate, pointing out the main characteristics of the rash and the infection. The literature upon the subject appears to be comparatively scanty and fragmentary. It is this fact which has led us to record our investigations and observations upon the cases dealt with in this paper, though the numbers involved are not very great. Out of 50 cases, five ended fatally (i.e., a mortality of 10 per cent.).

This disease, which occurs in newly born infants, is characterised by the appearance on the body of watery blisters, round or ovoid in shape and in some cases associated with severe toxic symptoms. It is distinct from the syphilitic pemphigus of infants, in which the rash appears at a later date and is always accompanied by other signs and symptoms of congenital syphilis. During 1927, and up till the end of September, 1928, we have investigated 50 cases which occurred in a borough with a population of 315,400. This year there have been 24 cases, the remaining 26 cases having arisen in 1927. Pemphigus neonatorum is not a notifiable disease; the infants in this series have been certified as suffering from pemphigus or "watery blisters," and came to our notice through being reported to the local supervising authority by the midwives in attendance, according to the rules of the Central Midwives Board. All the cases, except two,

occurred in a district which is poor and overcrowded, and where home conditions are very unsatisfactory. The majority developed in homes where the families lived in three rooms or less, and where overcrowding was prevalent. Four of the babies were delivered by a doctor, 45 by a midwife, and one in an institution (Table I.).

TABLE I.—*Illustrating Distribution of Cases among the Various Attendants, and the Termination.*

,, D ..	1	1	1	Totals ..	50	45	5

* Midwives A refers to a number of nurses practising in the district from nurses' homes in the borough. R = recovery. D = death.

There are two types of the disease, mild and severe, of which the first is much the more usual. In the mild form crops of blisters appear at intervals, the whole illness lasting from one to several weeks but unassociated with any general symptoms, the infant thriving and developing normally. The severe form resembles a widespread exfoliative dermatitis accompanied by marked symptoms of toxæmia—wasting, prostration, and high temperature—and usually ends fatally. In the cases we have observed the characteristic sign has been the appearance of watery blisters in the groins, round the umbilicus, and on the fingers and head (Table II.).

TABLE II.—*Fifty Cases showing Area of Body on which the Rash First Appeared.*

	Cases.		Cases.
Groin	17	Buttocks	2
Umbilical region	10	Arms	2
Legs	10	Fingers	2
Face	3	Back	1
Head and neck	3		

The first blisters commonly appear from six to ten days after birth, although this by no means holds good in every case. In our series the shortest interval was one day and the longest 21 days after birth (see Table III.).

TABLE III.—*Fifty Cases showing Day of Onset of Disease after Birth.*

Day.	Cases.	Day.	Cases.	Day.	Cases.	Day.	Cases.

3rd ..	2	7th ..	3	11th ..	1	Up to	
4th ..	3	8th ..	8	12th ..	2	21st ..	4

The size of the blister varies greatly, ranging from a little larger than a pin's head to that of a five-shilling piece. The smaller blisters not infrequently coalesce within a few hours to form larger ones. The contents of the blebs are clear at first, rapidly becoming turbid; the untreated blister breaks and discharges its contents, leaving a superficial, reddened, scalded-looking area. New epidermis soon grows over this, and no permanent scar is left.

Bacteriology.

The literature of the bacteriology of pemphigus neonatorum shows that various investigations have been made in this country and elsewhere and that several different organisms have from time to time been isolated from the blisters, but the weight of evidence points strongly to the *Staphylococcus aureus* as the organism most often present. Lereboullet and David,[2] who investigated a series of cases which were complicated by chicken-pox, were amongst those who isolated this coccus. We have not been in a position to make a bacteriological examination of the fluid in every case. In all the cases examined (with one exception, when a streptococcus was isolated) a pure culture of *Staphylococcus aureus* was grown from the fluid within the blebs. (We are indebted to Dr R. F. L. Hewlett, Pathological Department, Queen Mary's Hospital, Stratford, for having collected and examined the specimens in each case.)

Barber[3] says that "pemphigus neonatorum is contagious impetigo of the large blister or bullous type occurring in early infancy," and suggests "that a virulent coccus might, in the virgin soil of a new-born baby's skin, cause lesions of a different type from those seen in older children." Whatever the causal organism, there seems no doubt that the infection can be conveyed direct from one case to another by the doctor, nurse, or other attendant on the mother and infant. The fluid in the blisters appears to be the source of infection.

Infection and Spread of the Disease.

Pemphigus neonatorum is highly contagious; in a maternity hospital, unless immediately isolated, it spreads through the nursery with remarkable rapidity. Similarly, one case in the private practice of a district midwife may lead to a number of cases among her patients in a very short time. In the outbreaks occurring in our experience, no obvious septic foci which might account for the first case were found in those in immediate attendance upon the mothers and infants. Skin lesions were absent, and the nose and throat were examined with negative results. In only three instances was there a history of other illness in the home; in two cases older children were found to be suffering from impetigo and conjunctivitis, while in the third case one occupant of the house developed scarlet fever and erysipelas immediately before the confinement of the mother. Three of the infants were premature but only one was noted as weakly, this baby having also a harelip and cleft palate. A not insignificant fact was that one infant developed ophthalmia neonatorum, while three others had "sticky eyes"; in these cases the eye condition cleared up rapidly.

The origin of the first case in an outbreak is difficult to trace. In the individual case the organism may be introduced into the infant's circulation at the moment when the umbilical vessels are divided; this implies that pemphigus neonatorum is a blood infection producing a characteristic rash. But, if this were so, one would expect in all cases definite general toxic symptoms. In the majority of our cases the only manifestation of the disease was the rash. Falls[4] considers that the severe toxic type of the disease, ending fatally, is due to lesions on the abdomen spreading to the umbilical cord and producing a staphylococcal septicæmia. It seems more likely that the primary blisters are due to inoculation of the causal organism through some slight skin abrasion. The fact that the first blisters are most frequently seen on the "napkin area"—groins, upper thighs, and buttocks—or round the umbilical scar, lends weight to this theory. The fluid in the blisters seems to be the infecting agent. We have observed that if, when a blister bursts, the fluid is allowed to come into contact with the surrounding skin, a crop of fresh blisters frequently forms. In treatment the disease can be definitely limited by pricking each blister as it forms and carefully collecting the fluid, so that it may not come into contact with the adjacent skin surface.

The following two instances from the cases under our observation will serve to illustrate the way in which infection can be spread:—

Fifteen cases of pemphigus occurred in one midwife's (B) practice between April 14th, 1927, and Dec. 20th, 1927, resulting in one death. Within a period of three weeks from April 14th, 1927, four infants delivered by midwife B developed pemphigus; after each she underwent thorough disinfection. In spite of every precaution, including medical examination for any source of sepsis, she still continued to have pemphigus cases in her district. Owing to this she temporarily gave up work and was away on holiday for five weeks; during this period no case occurred in her district. When she resumed her practice six infants were infected within two weeks. Thereafter she was again medically examined for possible septic foci, but with negative result. The remaining cases in her practice in 1927

curred at longer intervals, when it was impossible to trace fection directly from case to case.

During the month of September, 1928, four cases of mphigus neonatorum occurred in the practice of two idwives who serve a comparatively small, isolated area of e borough where there had been no previous case of mphigus. There were four cases of pemphigus and one se notified as puerperal pyrexia within a period of 24 days. ll the evidence pointed to direct infection from case to case aving occurred in spite of apparently complete disinfection nd immediate handing over of the infected cases to the neral district nurses. We were quite unable to trace the igin of the first case. A possible explanation is that the home help " * engaged by the first patient came from a poor strict where several cases of pemphigus were known to ave occurred ; infection may have been brought by her, by friends from the same locality who visited this woman uring the lying-in period. No one in direct contact with e mother and infant had any sores or obvious septic foci.

Prevention of Spread.

(1) In an institution there must be rigid isolation mother and infant. The nurse responsible for ursing a pemphigus case must not undertake any her work in the hospital.

(2) In a district midwife's practice the midwife's uty is to seek medical advice at once. If she continues nurse the infected case she must not undertake ny further deliveries or nursing until the baby has een completely cured, and she herself has been horoughly disinfected. This procedure means a nancial loss for the average midwife. An alternative lan, though far from ideal, is for the midwife to pass ver the nursing of the mother and infant to the eneral district nurses, and then to undergo disin- ction of self, clothes, and midwifery bag, with ntents, before resuming ordinary duty. Obviously doctor or nurse suffering from septic skin lesions hould undertake a confinement or attend the mother nd infant during the lying-in period.

Treatment.

The method found by us most effective in bringing out rapid cure, and in preventing spread to other arts of the body, has been to give the infant a daily ath in a weak antiseptic solution, such as potassium ermanganate. The infant should be stripped and horoughly examined twice daily for fresh blisters. blister must be pricked as soon as it is discovered, sing every aseptic precaution, and carefully packing und the blister with sterile absorbent wool. Zinc nd boric dusting powder is then applied and the ffected areas are lightly bandaged. Greasy and moist pplications have proved less satisfactory. There is no need for further treatment in mild cases. The evere exfoliative and toxic type requires, in addition, ymptomatic and general stimulating treatment to aintain a satisfactory state. Gregorson [5] has eported good results from exposure of the infant to tra-violet light twice weekly.

End-results.

Five deaths occurred out of the total number. The ajority recovered completely within three weeks om the onset of the rash. Six cases were clear ithin one week ; in two other cases the rash per-

ABLE IV.—*Five Deaths from Pemphigus Neonatorum.*

sted to the fifth and sixth weeks respectively. These otracted cases had no general toxic symptoms ; the fants thrived well, but fresh crops of blisters peared at intervals, thus keeping up the state of fection (Table IV.).

* An unqualified woman who is paid by the local authority to lp for several hours daily in the duties of the household during e lying-in period of the mother.

Of the five infants two died at home while three died in hospital after a stay varying from one to three days. In all these cases the illness was short. The certified cause of death in four cases was " pemphigus neonatorum " ; in the fifth case death was certified as due to " convulsions and pemphigus neonatorum."

Conclusions.

After carefully considering all the factors connected with the cases described, we feel justified in coming to the following conclusions :—

(1) Pemphigus neonatorum is a contagious disease rarely seen later than four weeks after birth. (2) The infection is probably conveyed from one infant to another by the agency of the doctor, midwife, or other attendant. (3) There are two distinct types of the disease : (*a*) a mild type, causing little general disturbance ; (*b*) a severe type, which tends to end fatally. (4) The first appearance of the rash is most often on the groins. (5) The disease seems to attack healthy infants, but shows a predilection for those born and living under unhealthy conditions of space, light, and air. (6) The specific organism has not been isolated, but the presence of the staphylococcus in the blister fluid has been demonstrated in a majority of the cases. A mixed infection may supervene and cause death. (7) The best form of treatment is to keep the affected area dry and aseptic ; no moist preparations should be used. (8) Any midwife or doctor who has been in contact with a case should not attend another confinement until thorough disinfection of both person and belongings has been carried out. (9) The disease should be made notifiable and, when necessary, mother and infant should be isolated.

Clinical and Laboratory Notes.

CEREBRAL HÆMORRHAGE IN A HEALTHY CHILD

DUE TO TRAUMA, WITH RECOVERY.

BY G. H. R. HOLDEN, M.D. CAMB.,
AND
H. S. LE MARQUAND, M.D., M.R.C.P. LOND.

THIS case appears to us to be worth reporting because there are so few in the literature. The chief features of interest were : (1) cerebral hæmorrhage in a healthy child of 9 ; (2) hemiplegia of the internal capsular type, as commonly seen in the declining years of life ; (3) cerebral hæmorrhage due to a trivial knock ; and (4) the absence of any disease known to cause hemiplegia in children, or likely to cause disease of the blood-vessels.

A Case Described.

The patient, a healthy girl of 9, was dressing in her bedroom on July 29th, 1927 ; she stooped to pick out a pair of shoes from under a chest of drawers, one of the upper drawers of which was partly pulled out. On raising herself she hit her forehead just above the right eye against the edge of the open drawer. She walked a few steps to the bed, sat on it, and put on her shoes and tied them, meanwhile crying out to her mother, who came in. Then she fell on the floor, but was able to relate what had happened and to complain of pain in the region of the blow. A few spasmodic jerks in the left leg were observed, the child vomited once and then gradually lost consciousness. About ten minutes elapsed between the accident and complete coma.

When the patient was seen a few minutes later she was deeply comatose, the head and eyes were markedly deviated to the right, and the left side of the face was flattened and drawn over to the right ; paralysis of the left arm and leg

was diagnosed from the complete absence of tone in those limbs and knee-jerks and plantar reflexes were not obtained on the left side. There was no mark of injury on the forehead or elsewhere. After six hours she recovered consciousness and was seen to have a complete left-sided hemiplegia. She was able to swallow and to talk and there was no mental confusion. Conjugate deviation of the head and eyes persisted in some degree for about a fortnight. There was some precipitancy of motions and urine, but no marked incontinence. The temperature was normal; the urine was normal; there were no sensory symptoms. No other signs or symptoms developed and the patient steadily improved, getting out of bed three weeks later.

When examined four months later she showed the typical appearance of a partially recovered hemiplegic. The face had completely recovered. There was spasticity of left arm and leg with practically no loss of power or sensation, typical gait, and absent abdominal reflex with exaggeration of deep reflexes and extensor Babinski on the left side. Mentally the child was bright and happy, the urine and the blood pressure were normal.

When seen on Nov. 4th, 1928, 16 months after the accident, the patient had improved further. Spasticity of the arm and leg was less marked and the gait was nearly normal, but the left arm was still held flexed at the elbow and adducted. The child looked healthy and had grown considerably. She appeared mentally normal, but the school teacher reported that, compared to her previous condition, she was not at all receptive to new ideas and was inclined to be emotional over trifles. The reflexes showed no change and the urine was normal. The blood pressure was 134/80.

Diagnosis.

There seems to be no doubt that the lesion was a hæmorrhage into the right internal capsule. Embolism of one of the perforating arteries or of the middle cerebral artery is precluded by the fact that the symptoms did not develop immediately and also by the absence of any cause of embolism. A cortical lesion or a rupture of a meningeal artery is precluded by the extent of the paralysis, the conjugate deviation of the head and eyes, the flaccidity of the limbs, and the absence of irritative phenomena, as well as by the subsequent history. Both acute encephalitis and encephalitis lethargica start in rare instances with the development of hemiplegia. If the patient recovers, a condition of partial paralysis is left resembling the present condition of this child. The possibility of encephalitis was considered in this case, but was precluded by the absence of constitutional disturbance, by the speedy recovery from coma with no resulting mental symptoms, by the absence of signs of involvement of the mid-brain nuclei, and of myoclonic and athetoid symptoms. The interest lies in the hæmorrhage being caused by a trauma so slight that it left no mark a few minutes later, and the inability to discover any cause why a healthy child of 9 should have such a fragile "artery of cerebral hæmorrhage."

The previous history of the child sheds no light on the problem. Pneumonia with measles is the only illness from which she has suffered. The family history is excellent, the family is long-lived, three grandparents are alive, the parents are healthy, and the child has four healthy brothers.

Other Recorded Cases.

Cerebral hæmorrhage in children is rare; Osler [1] states that "apart from meningeal hæmorrhage, which is common as a result of the accidents of birth, hæmorrhage is rare in children, and we had no instance at the Johns Hopkins Hospital during my term of service." Sheldon [2] examined the post-mortem records of the Hospital for Sick Children. In 10,150 consecutive autopsies there were only 50 cases of intracranial hæmorrhage in children under 12. Excluding four cases due to birth injury, only three were due to trauma; the rest were caused by a variety of congenital and infective conditions. Sheldon's three cases are interesting. In the first the child had fallen against a cupboard some weeks previously; on the day of his death he vomited and became unconscious and paralysed in the left arm and leg. At autopsy a large clot was found in the right internal capsule. The second child hit his head against a table two days before death and at autopsy a hæmorrhage into the medulla was found. The third case was a boy who fell off a kitchen chair, becam unconscious shortly afterwards, and later showe convulsive movements of the right arm and l followed by paralysis. At autopsy the midd meningeal artery was found to be ruptured.

It is important to note from these cases that sligh trauma may cause not only meningeal hæmorrhag but hæmorrhage in the deep structures of the brai The long time which elapsed between the trauma an death in the first case is also interesting, and Mille has discussed this point in reporting the case of healthy child of 12 who died of an extensive subdur hæmorrhage seven weeks after a slight blow on th head. Even more difficult to explain are cases suc as those reported by C. O. Hawthorne,[4] in whic cerebral hæmorrhage occurred in healthy lads 17 and 14 years respectively without any history trauma, and without the discovery of any coincider disease post mortem.

A CASE OF MALIGNANT ENDOCARDITIS OF THE TRICUSPID VALVE ASSOCIATED WITH DAILY RIGORS.

BY A. J. SCOTT PINCHIN, M.D., M.R.C.P. LOND.,
SENIOR PHYSICIAN, HAMPSTEAD GENERAL HOSPITAL;
AND
H. V. MORLOCK, *M.C.*, M.D., M.R.C.P. LOND.,
PHYSICIAN TO OUT-PATIENTS TO THE HOSPITAL.

THE following case is recorded because of i rarity, and also because of the difficulty in establishi a diagnosis:—

A married woman, aged 25, came to the out-patie department on Oct. 26th, 1928, complaining of loss strength and weight, and gave the following history.

Seven months before she had suffered an attack "influenza" which was characterised by generalised joi pains, palpitations, and excessive perspiration. The atta confined the patient to bed for 14 days. After a further co valescence of 14 days she returned to work (store supe visor) and carried on until two months before admissio when she gave up because of increased fatigue; during th time her only complaint had been that every morning s had a shivering attack which lasted one hour, causing her perspire excessively, and leaving her weak. After givi up work the "shivering attacks" recurred daily up to t time of admission. The patient thought she had beco anæmic, and had lost about 2 st. in weight. There was history of a rash, œdema of the legs, pain in the chest, tender spots on the hands. In her previous history a family history there was nothing of importance. She h not had rheumatic fever.

Condition on Examination.—The patient was a thin, pa toxic-looking woman. Her tonsils were large, but n obviously septic; no tonsillar glands. The first left mo tooth was "suspicious." Nothing abnormal was detected the neck and lungs. The respiration-rate was 24. The ape beat of the heart was in the fifth left intercostal space; t area of cardiac dullness extended to the left to the ape beat, and extended to the right 1 inch outside right borc of sternum. On auscultation there was a musical systo murmur, heard best at the apex and over the lower end the sternum. Pulse, 120 regular; blood pressure, 110/6 spleen, palpable on inspiration, soft regular edge; le nil abnormal; urine, a trace of albumin.

The patient was sent into hospital with the provisior diagnosis of malignant endocarditis. Whilst in hospi she had a daily rigor, occasionally two in the 24 hours.

These rigors continued until the first molar tooth w removed, four weeks after admission. After this, t temperature rose daily to 103°–104° F. (but no rigc occurred) until the day of her death, eight and a half wee after admission. During these weeks the patient felt w and wished to get up, even on the day of her death, and t only alteration in the physical signs was a progressi anæmia (see blood counts). The cardiac condition remain unchanged, and no embolic phenomena occurred. Thr blood cultures, taken at the time of the rigors, were negati even after 15 days' incubation.

The absence of a positive blood culture, of embolism, d of changes in the cardiac condition lead to doubt to the accuracy of the diagnosis of malignant docarditis. The following differential diagnoses re considered: malaria, miliary tuberculosis, æmia, perinephric abscess, sinusitis, typhoid, lkæmia, *Bacillus abortus* infection. Appropriate thological and radiological investigation gave no idence of any of the above conditions. The blood unts were as follows:—

—	Oct. 26th.	Nov. 13th.	Dec. 11th.
d cells	4,128,000	2,324,000	1,677,000
hite cells	16,400	8,800	4,000
emoglobin	39·0%	24·0%	23·0%
lour-index	0·47	0·51	0·68
lymorphs	82·8%	78·8%	85·2%
mphocytes	15·2%	12·8%	14·0%
raline..	2·0%	2·8%	—
utrophil myelocytes	—	5·2%	0·4%
ast cells	—	—	0·4%

n Oct. 26th there were a few blood corpuscles in e urine, and also on Nov. 13th; their presence in r opinion is not sufficient evidence to establish e diagnosis of renal infarction. (The post-mortem ndings bear this out.)

Post-mortem Findings.—Only those bearing on the agnosis are given. Right and left pleura: excess of dark aw-coloured fluid. Right lung: no infarcts. Left ng: no infarcts. Pericardium: excess of dark straw-loured fluid. Heart: weight 13 oz. Left ventricle, nil normal, except toxic, pale muscle. Right ventricle greatly ated and filled with clots. Valves (mitral, aortic, and lmonary), nil abnormal. Tricuspid, two large vegeta-ns hanging from the left edge of the left anterior cusp; llow in colour; about ½ in. long by ⅜ in. wide; not ry friable or ulcerated. A few minor vegetations. No ngenital abnormalities. Spleen: large, toxic, fairly firm, infarcts. Kidneys: extremely pale, capsules stripped sily, no infarcts.

Discussion.

The diagnosis was in doubt during the whole of e illness; there were present only two of the four iteria which Sir Thomas Horder [1] gave in his mleian lecture of 1926 as necessary for the tablishment of the diagnosis of malignant endo-rditis—namely, pyrexia, endocarditis, embolism, d positive blood culture.

The rarity of the condition is one point of interest. 1920 Dietrich [2] reported a case in which the only idence of endocarditis was a systolic murmur heard l over the pericardium. Blumer,[3] in a review of 0 autopsies of malignant endocarditis, found only ree cases in which the tricuspid was involved alone. r Thomas Horder considered this condition of fficient rarity to give complete details of a case in s Lumleian lecture, 1926. Here, again, the only nical evidence of the endocarditis was an apical stolic murmur. Thayer,[4] in his series, found the rtic cusps involved in 66 per cent., the mitral in per cent., and the *right* heart valves as often as the itral (pulmonary and tricuspid).

The other point of interest which our case produces the occurrence of daily rigors. Although occasional gors are not uncommon in the disease, it is seldom at they are so frequent and regular as in this case. och,[5] in 1897, reported a pseudomalarial type of ptic endocarditis which was of 13 weeks' duration d had daily rigors. Leyden [6] reported a case in nich rigors occurred twice daily. In this case, as the other cases reported, the tricuspid endocarditis ve no characteristic murmur.

Our best thanks are due to Dr. C. R. Lane for his thological investigations.

ROYAL SOCIETY OF MEDICINE.

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE.

A MEETING of this Section was held on Jan. 25th, with Dr. F. E. FREMANTLE, the President, in the chair. A discussion on

VACCINATION AGAINST SMALL-POX IN THE LIGHT OF RECENT EXPERIENCE

was opened by Prof. J. C. G. LEDINGHAM, who said that the vaccination problem in its various aspects required review in the light of recently acquired knowledge. For many decades the study of vaccine virus had been limited to improvements in the technique of preparing lymph. One result of this detachment had been that lymph manufacture had come to be regarded as a sort of mystery cult. Outbreaks of cow-pox were frequent and ought to be scientifically investigated. It was not always possible to refer them to an origin in human small-pox or vaccinia, but available evidence undoubtedly pointed to contact with human vaccines. In a recent German outbreak the children of the milker had recently been vaccinated. Variolisation of bovines had sometimes been accomplished with remarkable ease; for example, in tropical countries where small-pox outbreaks had necessitated immediate supplies of lymph. There was experimental evidence that horse-pox was like cow-pox and due to the same modified variola virus. Most strains used in lymph institutes had been derived initially from human small-pox. Small-pox virus direct from man regularly produced a dermal response in the normal rabbit, but never when rubbed into the scarified skin. Repeated passage was necessary. Small-pox virus had, after accommodation to the rabbit, behaved like vaccinia when transferred back to man, so that the calf was not essential for the realisation of this modification of small-pox virus, a change which manifested itself by innocuousness for man and loss of contagious power. Initial passage through the monkey undoubtedly facilitated accommodation to rabbit and calf, but chiefly by providing a large supply of fresh potent virus. The complete change to vaccinia did not seem to take place in the monkey, as monkeys had given small-pox to unvaccinated attendants. Some element responsible for producing generalised lesions, as distinct from general invasion, was lost in passage to the rabbit or calf. This element might be another virus or the change might be one of general virulence-loss combined with increased affinity for skin tissue. There was good evidence that vaccinia afforded better protection against small-pox than small-pox did against vaccinia. The "attenuated virus" remained the most efficient immunising agent, but it was possible that variola vaccine of known recent origin might prove better still. There was no more pressing problem than that of the standardisation of the immunising powers of the viruses, and especially of vaccine strains. There was no satisfactory evidence that sheep-pox and fowl-pox had any intimate relationship with variola and vaccinia. Sheep and fowls were quite susceptible to experimental vaccinia. The vaccine virus produced a general disease, though it did not produce macroscopic lesions elsewhere than in the skin. Serious action at a distance was at least a possibility. In the rabbit grave illness or death after cutaneous vaccination with calf or other lymph of dermal origin was extremely rare, but some forms of virus, particularly those from cerebral or testicular sources, were liable to cause generalised skin lesions, especially after inoculation into the vascular system. There was experimental evidence that the addition of tissue extracts—e.g., testicular or renal—to vaccine virus had a very definite enhancing effect on the

virus response following intradermal inoculation. The inflammatory reaction was markedly greater, developed more rapidly, was more diffuse, and showed a tendency to early necrosis. Rabbits might occasionally become ill and emaciated or die, and necrotic lesions in the lungs might be found post mortem. In the speaker's opinion this illness depended solely on the stimulation by vaccinia of a latent pasteurellosis infection in the rabbits concerned. This mutual interaction between viruses, particularly the stimulation of a latent bacterial infection by a virus, was of great significance.

Types of Small-pox.

The speaker preferred the name "alastrim" to Garrow's "para-smallpox" because he had failed to find any outstanding differences between the form in this country and that in Brazil, West Indies, America, and South Africa. There was experimental evidence that the disease was a small-pox variant. It was readily communicable to the monkey by scarification. In the rabbit it produced typical vaccinia-like vesicles only after repeated passage, but material direct from man when inoculated intradermally produced characteristic reactions which were neutralisable by antivaccinia serum. On the rabbit's cornea the virus usually produced a positive Paul's test, and Guarnieri bodies were found. Paschen's elementary bodies were present in smears from early vesicles and a precipitin reaction had been obtained with alastrim material and antivaccinia serum. Experimentally vaccinia gave more certain protection against alastrim than alastrim gave against vaccinia. Some persons were so constituted that they did not respond to infection by an adequate immunising reaction; black races, for instance, were unusually susceptible to small-pox, against which they developed only a feeble immunity on recovery. Alastrim was probably a stable variant of small-pox. In England there had recently been a few localised outbreaks of the virulent form of small-pox, and it only led to confusion if deaths arising from this were added without reservation to the general mortality-rate of small-pox. Rajchman seemed right in concluding that two entirely distinct types of small-pox prevailed and bred true. The virulent form had a mortality-rate which fluctuated, in long waves of six to seven years, between 10 and 30 per cent. The mild type had minimal figures from 0·1 to 0·3 per cent. There was no evidence that minimal periods in the case-mortality of the virulent type were simply transitions towards an alastrim period with its negligible mortality.

Post-vaccinal Encephalitis.

These cases had shown a decided tendency to occur in groups, especially in country districts, and sometimes corresponded with the autumn prevalence of poliomyelitis or the spring prevalence of encephalitis lethargica. The apparent constancy of the period after vaccination at which nervous symptoms appeared might fit in with a theory which presupposed that some latent neurotropic virus in the vaccines was activated by vaccinia. There was no good evidence of vaccine virus producing lesions in the central nervous system unless it were inoculated directly into the brain. The histology was characterised by one very important lesion: perivascular demyelination, which was common to the encephalitis after measles, the myelitis of rabies treatment and certain forms of acute encephalomyelitis. Neither in acute poliomyelitis nor in encephalitis lethargica did perivascular demyelination appear, but the histology of these infections might or might not be modified by a concurrent vaccinia. Fortunately post-vaccinal encephalitis was rare. Practically all the cases had been primary vaccines and most of them had been children of school age. This might be due to the fact that in the allergic or accelerated reactions shown by partially immune subjects the virus was precluded from invading the central nervous system. There was no means of detecting beforehand the patients who possessed this peculiar liability, but their existenc was an argument for stressing infant vaccination an taking great care with the primary vaccination c older children and adults.

Is Universal Vaccination Desirable?

A certain small proportion of alastrim cases ha troublesome symptoms and profuse—occasionall hæmorrhagic—rashes. Alastrim might cause deat in feeble people or sufferers from other disorders It was a completely preventable yet not a death dealing disease when it attacked the unprotected Variola, however, had a tradition; it had alway ranked with plague and cholera as a death-dealin disease against which a civilised community mus protect itself. Hence the expensive paraphernalia c small-pox control was maintained, although th disease as it now manifested itself was almost harm less. Vaccination was cheaper than isolation an hospitalisation, and would abolish the disease alto gether. Vaccination and revaccination could "delive the goods." That being so, the problem of alastrir ought to be considered afresh and not as a tradition policy. No serious attempt had ever been made t explain to the man in the street what vaccination wa and what it was calculated to do. Cheap broadcas information and the help of an intelligent press wer needed. Experience of post-vaccinal encephaliti offered a strong argument in favour of primar vaccination in infancy and of reducing the dose t one insertion. This would also diminish the risk c sepsis. Under present conditions it might be debate whether compulsory vaccination were justified, an whether the prophylactic would not meet with fulle acceptance if it were purely optional and introduce to the people with the accompaniment of a sympa thetic and informative propaganda.

Dr. KILLICK MILLARD said that few people no regarded alastrim and small-pox as the same thing they were two entities—variants or mutants, bu fixed. There was no evidence that one changed int the other. The present administrative position wa eminently unsatisfactory and was becoming farcical to lump the two variants together in the same colum negatived the statistical value of the records. A far as the individual went vaccination and revaccina tion could "deliver the goods," but it was impossibl to point to any community in which they had effect tively prevented small-pox. In practice it was impos sible to vaccinate everybody regularly, and attempt to do so had always failed. During the last 24 year there had not been a single death from small-pox i Leicester, where the methods followed had bee isolation and hospitalisation. In face of that, was i possible to ask the whole population to underg vaccination which, after all, was a disease wit certain results, usually temporary, but sometime permanent, and occasionally followed by grave effect on the nervous system? It was necessary to recog nise the fact that major small-pox had left the country Unless it returned and could be controlled by n other means the people of this country would neve accept universal vaccination.

Sir GEORGE BUCHANAN said that the effect o advocacy of vaccination must depend on what state ment could be made about its safety. It was ver important that all possible risks, however rare, shoul be fully investigated. The problem was a universa one, not concerned with the British mentality alone It was important to see how far the disasters whic had occurred were the result of some coincidence o passing phase of some virus infection, and how fa they were due to some constant phenomenon asso ciated with vaccination. The League of Nations wa doing valuable work in collating evidence fron different countries.

Dr. S. MONCKTON COPEMAN recalled his own worl on vaccinia during the last decade of the las century, and expressed his gratification that hi findings had been confirmed by recent work. He ha never once failed to carry either small-pox or vaccini to the monkey, though the former could not b

nverted straightway to the latter in that animal. was possible that inoculated small-pox, rather an ordinary small-pox, might be the source of cow-x. He had obtained a number of excellent strains vaccine lymph from cow-pox. When the first tbreak of alastrim had occurred in this country in 03, Sir Clifford Allbutt had said, "Well, then, if is is small-pox, there is an end to all diagnosis"! ere was a difference between small-pox and alas-im, for a certain number of cases would take vaccina-n during convalescence from alastrim. Cultures small-pox material in the fertilised hen's egg in 95 had produced an excellent strain of variola ccine, but this was said to have led in South African tives to severe generalised vaccinia and some aths. Vaccination had suffered from the "poor-y taint," and it would be better when it came der the public health authority.

Dr. R. P. GARROW said that when speaking of "two seases" he had meant no more than a "fixed riant." For all practical purposes the two were fferent. Mild small-pox had never been absent m his district for eight years and was not likely be, for people had discovered that an attack was better investment than vaccination. They got ree weeks in hospital, where they were very com-table, and their insurance money when they came t. The disease was not worth preventing. Much mage had been done to the cause of vaccination assuring people that small-pox was a loathsome d fatal disease; it was neither—nowadays. Among 00 cases he had never seen anything resembling morrhagic or toxic phenomena. It was extra-dinarily difficult to get at the truth. He had sited districts where medical officers of health had imed that the disease was increasing in virulence d had found no change whatever. He had been red of any views he had ever held about the advisa-ity of compulsory vaccination. He challenged as sleading Dr. Millard's statement that vaccination l not protect the community; there were completely ccinated communities and these were completely otected. To admit that the community would not ail itself of vaccination was not the same thing as claring that vaccination protected the individual d not the community.

Sir WILLIAM HAMER argued the view that post-ccinal encephalitis was a fortuitous event, due to incidence in time of vaccination and an influenzal other form of encephalitis.

Dr. R. W. JAMESON pointed out that officially riola major and minor did not exist; there was ly one disease. This hampered scientific work. o one could say that the victims of "post-vaccinal cephalitis" would not have died if they had not en vaccinated, and the theory that vaccination rely activated another virus would not comfort e relatives. The statement that it did not occur infants was unreliable, as the ordinary practitioner l not know what a baby died of and certified the se as "marasmus" or "convulsions" when it ght be encephalitis. In fact we knew nothing at about vaccination except that it did not usually l babies at once and that it conferred some tem-rary immunity; we did not know what it did to e children afterwards. To talk about universal ccination in non-epidemic periods was as useful as try to persuade people to stay at home for fear street accidents. Vaccination should not be vocated until something was known about it.

Dr. MAJOR GREENWOOD applied to the discussion e remark of Sherlock Holmes: "You have con-cted a very consistent investigation, Watson; I not at the moment remember any conceivable nder that you have omitted to make." He garded Dr. Millard's remark—to which Dr. Garrow l objected—as perfectly logical. A dreadful ount of nonsense was perpetually talked about ccination, and that was the difficulty. In Jenner's ssical paper no mistake was omitted that could ssibly have been made, and there was a good deal evidence that Jenner had been a rogue. Unfortunately the antivaccinationists could never get away from Jenner's roguery, and the trouble was that Jenner had been perfectly right in his guess. The difficulty of the orthodox school was that they could never decide which horse to ride. They would talk about vaccination having modified the epidemiological history of small-pox, whereas small-pox had changed many times before vaccination had ever been thought of. Why should they not treat vaccination like any other form of prophylaxis and advocate it only when circumstances of special risk were incurred? The whole problem of herd immunity and individual immunity was in its infancy and nobody knew the truth about it.

Dr. J. A. H. BRINCKER agreed that alastrim was a stable variant, and related the history of vaccination among London school-children during the last few years. Among some 6000 vaccinated only one case of encephalitis had occurred. He supported Prof. Ledingham's conclusions.

Dr. S. F. BEDSON urged the importance of seeking some safer method of vaccination. In foot-and-mouth disease, distemper, yellow fever, and fowl plague it had been found possible to immunise by an initial dose of formalised killed virus consolidated later by a dose of live virus. It might be possible to deal with small-pox along these lines. He could not agree that post-vaccinal encephalitis had no connexion with vaccination; it would not occur if the virus did not generalise, a danger which would be decreased by a divided method.

Dr. W. K. SIBLEY said he had never seen a case of generalised vaccinia. Vaccinia was a localised disease of the cow's udder and he did not see why it should ever generalise. He asked why four inoculations should be necessary for vaccination when one was sufficient for other infections like syphilis.

Prof. ARTHUR ELLIS supported Dr. Bedson's plea, as he had seen four healthy children die of post-vaccinal encephalitis within three weeks. He considered that we were being neglectful and negligent in this matter.

Prof. LEDINGHAM, in reply, said that this was not the time to hold exaggerated views about the seriousness of things like post-vaccinal encephalitis. The problem could only be solved by further experiment. We had not got an efficient vaccine virus and research on a large scale was not being carried out; in fact, the need for it had only recently become apparent.

MEDICO-LEGAL SOCIETY.

A JOINT meeting of this Society with the Maternity and Child Welfare Group of the Society of Medical Officers of Health was held on Jan. 24th, Sir WILLIAM WILLCOX, President of the Medico-Legal Society, being in the chair. A discussion on

CRIMINAL ABORTION AND MEASURES NECESSARY TO REDUCE THE SALE OF ABORTIFACIENT DRUGS

was opened by Dr. F. J. MCCANN, who said that the practice of abortion was undoubtedly increasing and that on an average 25 per cent. of abortions were criminal, although the figures varied with the locality. Some women aborted easily; others could be subjected to the greatest possible internal and external violence and yet fail to abort. For the benefit of legal members who did not understand the anatomy of abortion, Dr. McCann then showed a number of diagrams and described the relations of the female pelvis. A distinction between the "medical man" and the "unskilled abortionist," he said, was not justifiable, for many unqualified abortionists became highly skilled and many doctors were quite unskilled. All kinds of instruments had been used, and there was no doubt that a woman could successfully pass an instrument on herself. Usually her effort was fatal, but some successes had been attained by the injection of soapy fluid into the uterus through a catheter. The one thing that haunted the abortionist, skilled

or unskilled, was shock, which could neither be foretold nor prevented. Some women were far more liable to shock than others. Factors in its production were the state of mind in which the abortionist's patients came to him and the fact that they were usually wilful and disobedient, insisting on keeping at work. Rest in bed was more necessary after artificial than after natural abortion.

Drugs used for abortifacient purposes were of two types: emmenagogues and ecbolics. In Austria abortion by drugs was said to be diminishing and giving place to mechanical means; phosphorus had been used in Vienna and was said to cause retroplacental hæmorrhage. Arsenic and mercury might cause severe vomiting and diarrhœa without producing abortion. Most terrible of all was diachylon; for one penny a woman could get enough diachylon plaster to poison her, cause abortion of her child, and leave her a mental and physical wreck. Something must be done to regulate its sale. THE LANCET had done a very good work in inquiring into the contents of the pills and potions advertised as abortifacients. One sample analysed had contained colocynth, aloes, ergot, borax, sulphate of iron, and hellebore. The advertisements were less common than they had been, but the trade went on. No alteration in the law was necessary. The Home Secretary and the police had only to be encouraged and the whole thing could be stopped. Dr. McCann suggested that as the outcome of the meeting the Home Secretary should be asked to receive a deputation to discuss what could be done to stop the advertisement and sale of abortifacient drugs; that lead should be included in the Dangerous Drugs Act; and that a council should be formed to inquire into and report on all these proprietary preparations before they were exposed for sale.

The Paramount Importance of Public Opinion.

Dr. R. A. LYSTER said that the law might be considered satisfactory if it were energetically administered. The law dealt with the situation in a drastic fashion, originally from the moral aspect—the desirability of preventing evil-doers from escaping the consequences of sin—but more especially later from the point of view of the general sanctity of human life. There was a tendency to alteration in that attitude to-day; it was very unusual nowadays for a charge of murder to be instituted as a result of destruction of the embryo. The point of view taken by most medical officers of health now was that of the serious effect of abortion on the infant mortality and maternal invalidity rates. A successful abortion often meant a damaged woman and an unsuccessful one meant a damaged woman and a damaged child. In his opinion fatalities were tending to decrease, but it was doubtful whether damage was decreasing as well. The questions that called for serious consideration were: What was to be the future of abortion? Was the public modifying its view about the criminality of the act? What would be the effect of the incidence of an enormous number of voting women? Would drastic measures be likely to have a successful issue? And could the law be tightened up? Diachylon had recently been included in Part I. of the poisons schedule, but it was doubtful whether this had had any appreciable effect on the general tide of abortion, although lead was the surest and most certain abortifacient known. A great deal of nonsense was talked and written about abortion. The only certain abortifacient was a general poison; lead would only cause abortion when it had produced general poisoning. It was no use legislating unless the people were behind the law. Dr. Lyster was doubtful what the real opinion of the people was. Abortion was a very grave national danger and likely to affect the physique of mothers and children, but to plunge too precipitately into any campaign might cause more harm than good, as there might well be a revulsion which would produce more difficulties than at present existed.

Sir BERNARD SPILSBURY said that everyone engaged in medico-legal work must be appalled at the amoun of abortion that was going on, and the estimate o 25 per cent. as criminal was certainly not an exag geration. The change in fashion was striking; i recent years the drugs used were not often thos which endangered life, but there was no means o judging to what extent they were successful. Man were comparatively harmless and very useful fo other purposes; they must frequently be taken wit success by those women who aborted readily. Th history of an instrumental interference almost alway revealed that the woman had first had resort t drugs, though seldom dangerous drugs, the use o which was largely restricted to doctors and chemist who had easy access to them. Quinine had been ver largely used just after the war, and in one case hydras tine had been procured by a chemist's assistant Pituitary extract did not lend itself to administratio by a layman, as it was only effective hypodermically On the whole the dangers and use of ecbolic drug and of general poisons were very limited at th present time, and the number of cases of poisonin by drugs used for ecbolic purposes had very greatl diminished. The speaker had not seen a fatal cas of lead poisoning since 1918, and poisoning fro mercury, phosphorus, arsenic, and cantharides ha been comparatively rare at all times. It was a ver different story when he turned to the heterogeneou action drugs advertised for female irregularitie Drastic purgatives were very largely sold for abortio and it was extremely doubtful whether their sa could be restricted without interfering with the legitimate use. As abortifacients these drugs eith failed, or succeeded in producing an abortion tha was exactly like a natural one and was not followe by the dangers of instrumental interference. The was, therefore, very little information about then A host of other drugs were advocated, many of the having apparently little value. Nevertheless n drug—not even pennyroyal which had a reputatio as an abortifacient—could be classed as perfectl harmless, for its reputation must be founded on som success, and the woman who miscarried easily migh abort after it. Many patent medicines were used i this way, for instance, Beecham's pills, but their sa could not be restricted when they were in such gener use. In the present poisons schedule we had such restriction as limited the use of drugs that were reall dangerous, and the rest should be left to the educa tion of the general public. Abortion was not popu larly regarded as a crime, and often no one was mor surprised to hear she was doing wrong than a woma who gave another one advice on how to get rid of baby. Despite his fearful results, the profession abortionist was a popular person. Instrument means were being used more and more. The speake held an autopsy on a case of this kind about onc every ten days. Abortion was a danger, wheth skilled or unskilled. Haste and secrecy were essenti to any illegal act and this ensured unsatisfactor conditions of cleanliness and care. There was grav risk of sepsis—the commonest of all dangers. Th gross injuries of earlier days were seldom encountere now; lacerations were rare, but sepsis, hæmorrhag and shock persisted and death resulted from then The most fashionable method during the last 15 o 16 years had been the injection of fluid into th uterus; it had perhaps been introduced from th Continent by Belgian refugees. Apart from shoc this was fairly safe and seemed to be successful in good proportion of cases. With the increase of know ledge there had been a change in the methods, an skilled operators now favoured electrical mean Only by educating the public into the wrongfulne and especially the dangers of abortion could we hop to bring about any improvement.

A Gynæcologist's Experience.

Mr. H. BECKWITH WHITEHOUSE said that most o the preparations sold were frauds on the credulity o the public. He was amazed at the extraordinar moral mentality of the woman who had made up h mind to terminate a pregnancy; no persuasion o

[1] THE LANCET, Dec. 10th, 1898, and many succeeding issues.

eat would turn her from her purpose. Out of five nen who had asked him to procure abortion for m during the last six months, four had been ried. Two of these had persuaded other doctors do it on medical grounds; one had had pelvic mbosis and had been in bed since August. A d had done it for herself by injecting hot water her bath and had had a stormy convalescence. fourth had taken several colocynth and aloes s followed by ergot, had partially aborted, and had a severe hæmorrhage. The only single woman he five was continuing her pregnancy. Abortion he popular mind seemed to be a matter of small nent, and most doctors must have been acces- es after the fact at some time or another. The of lead had now disappeared from Birmingham, pennyroyal, aloes, and ergot were now the ionable drugs of the obstetric underworld, but ause of their uselessness they were largely being laced by instruments. The appliance most often nd was the "slippery elm," a long tent of elm d inserted in the cervical canal. It was on record t a woman had successfully passed a knitting dle on herself 35 times. The speaker had removed elm tent from the bladder and a bone crochet dle from just below the liver. This latter patient's had been saved by her sister—a trained nurse—o had insisted on a vaginal douche and sterilisation the instrument before the woman passed it. It s not the drug so much as the dose; in a hyper- sitive woman a large or even a reasonable dose of armless drug in common use might induce abortion. ther argument against restriction of the sale of gs was that it would lead to more extensive use of ruments. Restrictions of sale would not stop minal abortion and—apart from lead—would do re harm than good. Often a woman who had d various drugs in vain would think twice before ing further steps. The longer the products of ception remained in the uterus the less likely was maternal instinct to be perverted; the first two three months were the dangerous period. The ention of women should be called to the risk to lth and happiness entailed by abortion, a risk ich did not end with the abortion. Recent work on corpus luteum had suggested that if pregnancy e violently ended a lutein cyst was likely to result. ortion might have some more lasting effect than was pected. Women had a very real regard for their aries, and might hesitate to procure abortion if they ught they ran a risk of losing the ovary thereby.

The Legal Position.

Mr. H. D. ROOME, after referring to the case of "Reverend Francis Bacon," said that the law ded no strengthening; if properly applied it was f, clear, and thorough. It was contained in two rt sections of the Offences Against the Persons t, 1861. The first made it a criminal offence for any son to use an instrument or any other means atsoever or to administer any poison or other xious thing whatsoever with intent to procure carriage of any woman, whether she be or be not h child, under a penalty of penal servitude for life. e second section, made law for the first time in 1861, hibited the supply or procuring by any person with like intent either of instruments or poisons or any er noxious thing whatsoever, on a penalty of five rs' penal servitude. A noxious thing had been ined as any preparation administered in quantities ely to produce abortion. The quantity was portant, but if a reputed poison were used with ent to procure abortion the quantity would be elevant. Ecbolics within the poison schedule were ot, savin, arsenic, cantharides, belladonna, tartar etic, and lead. There was no infallible ecbolic, but h things as quinine, aloes, oil of juniper, gamboge, nyroyal, and hellebore, if administered at the tical time, were likely in many cases to be successful. mething might be done by scheduling some of these gs, though it would be impossible to restrict them . It had never been murder to destroy an embryo, t it was now rare to indict an abortionist for murder, even if the woman died. The legal test was whether, as a reasonable man, he would be likely to anticipate that death or grievous bodily harm would be likely to result from his operations. This put a premium on the skilled operator, who was less likely to expect mishaps than the unskilled. The real cure for abortion was a change in public opinion. When it was no longer regarded as shameful for an unmarried woman to perform the most natural act in the world, when there was more charity, when public opinion came into line with recent legislation which provided maternity benefit for married and unmarried alike, when there was more tolerance, so that the unmarried mother could bring up her child without reproach, then alone would a real and permanent cure for abortion be found.

Dr. ROCHE LYNCH thought that drugs were just as much in vogue as ever they had been; they were always tried first. Often the drugs supplied had absolutely no abortifacient properties; in one case a girl had spent £40 for potions consisting of iron salts, caffeine, starch, and traces of garlic, clove, and sage. The doses were very small and the sale was a rank swindle; steps might well be taken to stop that sort of thing. Much the commonest of the more potent drugs used was aloes, usually in combination with iron. Drug vendors were scared of preparations that came under the Poisons Act. It would be practically impossible to put lead under the Dangerous Drugs Act, and lead abortions would not thereby be stopped. In one case abortion had been procured by drinking vinegar in which lead piping had been steeped for a week or two. The only possible limitation would be to stop the sale of this class of drug by any except qualified chemists.

Miss SUSAN MUSSON (Secretary of the National Council for the Unmarried Mother and Her Child) said that her Council was very anxious that something should be done. The death-rate among illegitimate children was nearly twice that among legitimate. The girls with whom they dealt had usually not the slightest idea that they were doing anything illegal in procuring abortion; even workers did not realise the dangers. She quoted instances of girls spending enormous sums on different preparations; gunpowder in gin and "hiccory piccory" were quite often used. Many social workers could provide evidence if it could be taken up. Newspaper advertisements continued to appear; Old Moore's Almanack in particular was full of them. If something could be done to stop them it would go a long way.

Sir WILLIAM WILLCOX agreed that public opinion was the important factor and mentioned that "hiccory piccory" was the old preparation of aloes and colocynth, known as "hiera-picra."

Lord RIDDELL said that the Advertising Association had taken up the question of abortifacient advertisements in a drastic manner and had persuaded a number of papers to refuse them. He would be glad to receive the names of any offending papers with a view to sending an admonition from the Association. If an advertised drug was claimed to "remove all female obstructions however caused," it was either a fraud or an abortifacient. Criminal prosecutions by private persons were serious and expensive, and, if unsuccessful, were apt to put the prosecutor in an awkward position. In his experience the police were not backward in taking steps when members of the public supplied them with evidence. There was no doubt that the disgrace attending the birth of an illegitimate child was responsible for a great many abortions and maternal and infant deaths, and a vast amount of invalidity. It was useless to shut our eyes to the fact that many women did not regard abortion as a moral offence; what really mattered was the psychological situation, the heart of the individual. If the bulk of the women in the country believed that abortion was not wrong, then it would go on.

Dr. NORMAN HAIRE emphasised the fact that there was a strong trend of opinion among people of high moral views that abortion was not a moral offence. In Russia and Czecho-Slovakia it had been legalised

up to the third month, the woman going before a commission in a town or the medical officer of health in the country to obtain permission. It would be impossible for any law to prevent abortion by drugs. A census among doctors and lawyers asking how many of them had attempted to procure abortion in their own families would—if answered truthfully—produce surprising results. In the last issue of the *British Journal of Actinotherapy* a new contraceptive appliance had been described, depending on the ionisation of quinine in the vagina. It was to be used "soon after connexion." He would like a legal ruling whether, if it were used next morning, or the day before the expected menstrual period, it would become an abortifacient. If a patient, to whom a doctor had given this contraceptive in all good faith, used it a few days after the period had failed to arrive, would the doctor become an accessory before the fact of attempted abortion?

Prof. LOUISE MCILROY said that she came across an enormous number of cases. She thought that abortion would go on as long as it was helped by the medical profession who gave assistance afterwards without betraying the patient or being able to take any steps to prevent further attempts. She would like to know if the profession would always have to wait until the patient died before informing the police.

The PRESIDENT said that the police had great difficulty in getting people to come forward with evidence against abortionists, and the authorities felt very strongly that it was most undesirable to institute proceedings without strong grounds. The opinion of the public and of women about the moral aspect of abortion had been mentioned; the opinion of the doctors had also changed profoundly. A departmental committee on poisons was sitting, and it was not unlikely that the law on this subject would soon undergo considerable modification.

MEDICAL SOCIETY OF LONDON.

AT a meeting of this Society on Jan. 28th, with Dr. WALTER CARR, the President, in the chair, a discussion on

STARVATION IN TREATMENT

was opened by Dr. E. I. SPRIGGS. Starvation, he said, was the fate of many organisms, but man had been able to fight this risk by preparing and transporting food; so that it was possible to relieve individuals and nations who through destitution or famine were unable to procure it. Fifteen years ago starvation as a natural phenomenon among mankind seemed to be dying away, but during the late war millions of people underwent semi-starvation.
